Progress of Medical Science.

Boston Medical and Surgical Journal, January 28, 1909.

The Cold Storage of Poultry.—W. F. Roos says that it makes no difference whether fowls are drawn or not before being placed in cold storage, but they must be perfectly fresh before they are stored. As they are kept below zero, no chemical or bacterial changes can occur in them. He refers to a mamal uncovered by a landslide in Siberia. It had evidently died by accident, and, although there perhaps fifty thousand years, its flesh when thawed was perfectly sweet and formed a palatable and agreeable food eaten without harm by both animals and men. The danger, if any exists from frozen poultry, must come from improper handling after it is removed from storage. Markets are often uncleanly, and the same water is used to soak the birds overnight before they are placed on sale. This water-soaked bird has an insipid and often disagreeable flavor and quickly decomposes. If they are not quickly sold they are again placed in storage, and if sold later they may be dangerous. After removal from storage the undrawn birds kept better than drawn birds. This is probably due to the fact that the aerobic bacteria which prepare the way for the more profound processes of anerobic putrefaction in the entrails are destroyed in a great measure by freezing. All in all, it is better to draw the fowls before they are stored. The customer should buy the frozen fowl and let it thaw in the air.

Laryngotomy and Laryngectomy for Cancer, with Report of Cases.—D. C. Greene, Jr., reports four cases, one of a man sixty-four years dying from collapse eight hours after operation; the second, a man of sixty-one years, living in good health three years after operation; the third, a man of fifty-eight years, living in good health eighteen months after operation, and the fourth, a man of fifty-two years, living nine months after operation, but with probable recurrence. The author says that with attention to a certain essential details in these operations, the mortality can be kept at a comparatively low figure. These details comprise a careful selection of cases, attention to oral cleanliness, and the avoidance of shock by the use of atropine before operation, local use of cocaine during it, and the Trendelenburg position during the second stage Inhalation pneumonia should be avoided by the Trendelenburg position during operation, rectal feeding, and the elevation of the foot of the bed after operation. The technics of both operations are fully described according to the methods of Semon, Butlin, and Jackson.

What Type of Operation Is Best Adapted for the Relief of Disease of the Frontal Sinus?—E. A. Crockett says that in acute frontal sinus infections the use of the ice-bag over the sinus and of adrenalin solutions is all that is necessary. In the severer cases the middle turbinate, or at least a portion of it, should be removed under general anesthesia. Cocaine is not sufficiently anesthetic. The nose should not be packed. In chronic cases, and when the infection involves merely the frontal sinuses and anterior ethmoidal region, with perhaps the antrum filled by drainage, a simple type of operation should be performed, the antrum being tapped and washed out at the same time. Under primary anesthesia the middle turbinate and ethmoidal region should be cleaned out as far back as the bulla with a Luc forceps. This is easy for one accustomed to work in the nose. Care should be taken not to disturb the cribriform plate. If this operation does not relieve the pain, a probe can easily be passed up the frontal nasal duct. For the more severe cases the Killian operation is undoubtedly the best for hospital patients, but this should be avoided as far as possible in private practice on account of possible deformities. If the chronic case is accompanied by orbital abscess and the infection is through the floor of the sinus, the usual operation for chronic cases plus the opening of the orbital swelling will suffice. In cases in which there is caries of the orbital plate of the ethmoid or the sphenoid or posterior ethmoid cells are involved, the Killian operation is preferable, at least in hospital cases. The author has had no complicating meningitis in his cases. The nose should not be packed, and the sinus but lightly. In seventy-five cases a secondary intervention has been necessary in but three. He has had some trouble with sepsis, but only when it was present before the operation.

Some of the Vagaries of the Obstetrician from the Standpoint of the Pediatrician.—J. L. Morse comments on the subjects of cyanosis and congenital heart disease, phimosis, breast feeding, artificial feeding, premature infants, icterus and sepsis, autointoxication, and congenital deformities in the newborn. He says that most obstetricians refer cyanosis to heart disease, but it may be due to an enlarged thymus gland, atalectasis, pulmonary apoplexy, diaphragmatic hernia, cerebral hemorrhage, or sepsis. Atalectasis is the most common, and in his experience cerebral hemorrhage and sepsis come next. There are many forms of congenital heart disease besides patent foramen ovale. There is no benefit from placing the baby on the right side. Phimosis is overdone. In most instances the breaking up of preputial adhesions with a probe and retraction meet every need. Obstetricians do not as a rule appreciate the importance of breast feeding. Almost the only contraindications are tuberculosis or some serious disease of the mother. Breast feeding should not be given up unless continued trial shows that the milk cannot be regulated so as to agree with the baby, or the mother's health is being seriously impaired. In making artificial mixtures, the obstetrician does not understand what creams are. The author believes them to be any milk containing more than four per cent. of fat. Top-cream after the bottle has stood eight hours may contain 16 per cent. of fat. Consequently the amount of this ingredient in the baby's food is often in great excess. Premature infants are often given too strong mixtures and overfed. Jaundice may come from sepsis, but here we generally have in addition fever, a bad general condition, and hemorrhages. Calomel is not needed for the simple icterus neonatorum. Sepsis is often overlooked and is very common. It may cause cyanosis, jaundice, hemorrhage, hemorrhagic disease of the newborn, digestive disturbances, bronchitis and broncho-pneumonia. It is due in every instance to germ-entrance. Dirty water often enters the mouth during the bath and when the mouth is cleaned with the finger. Autointoxication from absorption of bowel contents is not uncommon. The bowels should be cleared out with castor oil. Every newborn child should be most carefully examined for the presence or absence of congenital malformations. Cleft palate may occur without harelip.

New York Medical Journal, January 30, 1909.

The Serum Diagnosis of Syphilis and Its Clinical Value.—This question receives a general consideration from W. J. Butler. His personal results were as follows: Of the 150 cases of syphilis, suspected syphilis, latent syphilis, and metasyphilis examined, 123 were positive and twenty-seven negative, making eighty-two per cent. of positive reactions. This corresponds quite closely to the later results obtained by various investigators in these cases. The gross figures, however, do not indicate sufficiently close the results obtained by the reaction at different stages of the disease, as will be seen from the following: Of ten cases in the primary stage, including all cases prior to the appearance of secondary symptoms, all, or 100 per cent., gave a positive reaction. Of thirty-six cases in the secondary stage, thirty-four, or ninety-five per cent., gave a positive reaction. Of thirty-one cases in the tertiary stage, twenty-nine, or ninety-four per cent., gave a positive reaction. Of sixteen latent cases, nine, or fifty-six per cent., gave a positive reaction. Of fifty-five cases of parasyphilis and visceral syphilis, forty-one, or seventy-six per cent., gave a positive reaction. Two cases in which the patients had been treated energetically by mercury, the one with injections and the other with inunctions, gave a negative reaction. The latter case had, before the beginning of the treatment, given a strong reaction. The author says that a positive reaction may be regarded as an indication for antisyphilitic treatment. We cannot advise its discontinuance if the test becomes negative later. We should not await external manifestations of the disease before beginning treatment.

Pathology and Treatment of Chronic Gonorrhea.—A. A. Uhle and W. H. Mackinney ascribe the apparently mild catarrhal condition of the urethral mucosa to the presence of deeply situated gonococci in a low degree of activity. In the anterior urethra these chronic changes are particu-

larly confined to Littre's glands, which run obliquely from before backward, most prominent on the upper wall of the urethra, some being quite superficial, others extending deeply even into the erectile tissue. The lacunæ of Morgagni, likewise here present, are also involved. They cannot be regarded as true glands, but as crypts or depressions in the mucous membrane. In the posterior urethra glandular structures are rudimentary, but their pathological equivalent is found in the numerous prostatic ducts and the ejaculatory ducts. The authors discuss the tissue changes which are set up in these. Three varieties are recognized: catarrhal, follicular, and parenchymatous. For treatment the authors advise urethral irrigation, massage of the prostate, and then careful examination of the urine passed. The silver salts are overestimated, for much of their repeated value is due to the flushing of the canal which their use entails. In the later stages, astringent injections, passage of sounds and dilaters, prostate massage may all fail, owing to the weak natural resistance of the tissues toward the gonococcus. Strong resistance may require only general hygiene and simple internal remedies. In closing, the authors say that in their opinion we have at our disposal no drugs which possess the power of penetrating the mucous membrane and the glands and ducts communicating therewith to a sufficient degree to destroy all the gonococci, and, further, that all the means used in the cure of subsiding and chronic gonorrhea, be they injections, instillations, instrumentations, massage, etc., have as a basis of action the production of local, artificial congestions, which make possible the activity of the natural defenses of the body against the continued activity of infectious organisms.

Preventive and Abortive Treatment of Mastoiditis.—W. S. Bryant says that the prevention of a patient from mastoid inflammation is conditioned upon an integral condition of the upper air tract, and this means good hygiene and sometimes operative or medical intervention. These latter are necessary when local conditions have passed beyond simple functional disturbances with structural and tissue abnormalities. If functions alone are at fault, local applications will be found of benefit. In general infection the case of the upper air tract will safeguard against mastoid involvement. As soon as infection of the middle ear is suspected, treatment should begin. As a rule, we require more drainage than we can expect from one tube, and consequently we should incise the membrana tympani. Rest in bed should be insisted on if there is any evidence of incipient mastoid trouble, a saline purge given and hot water applied. Hot douching with a boric acid solution should be done hourly when awake. We may also use cupping, blood letting, and Wilde's incision. Nasopharyngeal treatment is the text for prevention and abortion of mastoid inflammation.

Electricity in the Treatment of Fractures.—C. O. Files believes that the processes of repair are essentially the same in fractures as in sprains, for all the vascular structures are repaired in practically the same manner. If the swelling and pain of a sprain are relieved and the injured tissues are cured by electricity, then the fractured bone will be restored by the same process. The swelling and pain, or, in other words, the inflammatory changes, are as unnecessary in a fracture as in an external wound. The conditions are in fact more favorable in a simple fracture, because there is no occasion for antiseptic treatment. The tight bandaging of a broken limb is an effort in the right direction, in preventing too much extravasation, and in favoring absorption, but the result is almost nil as compared with the efficiency of electricity. Moreover, the author says that in fractures there is a period of from seven to ten days, and sometimes longer, when there is no progress whatever in the work of repair. This time is spent in bringing to the parts an excess of material and in laboriously absorbing that excess. The whole trend of knowledge in regard to the therapeutics of electricity goes to show that this period may be diminished, if not eliminated, and that the subsequent stages of the process of osseous regeneration may be much hastened by the careful use of electricity.

Journal of the American Medical Association, January 30, 1909.

Classification of Pulmonary Tuberculosis.—L. Brown says that no perfectly satisfactory classification of pulmonary tuberculosis has been achieved, though it has often been attempted. It is a relapsing disease, and the results must therefore be considered under two heads, immediate and ultimate. Sanatorium patients must be classified on admission, on discharge, and according to final results. The classification should take into account not only the amount of disease in the lung, but the actual condition of the patient. Symptoms, as well as the pathological and general conditions, must be considered, and the divisions should be as sharply separated as possible. He reviews and criticizes the various classifications that have been proposed, and points out the difficulties that are met with, finally giving the classification which he thinks best, and which is somewhat modified from that of the National Association for the Study and Prevention of Tuberculosis. There are no important alterations in the classification of the incipient stage, and the definition of "moderately advanced" has been only slightly altered and simplified, that of "far advanced" is the same as in the other. As to the classification on discharge, the definitions have been but little altered: "cured," "apparently cured," "arrested," when the symptoms have been stationary or retrogressive, with absence of all constitutional symptoms; "improved" when the constitutional symptoms are lessened or absent, but cough or expectoration still continues with bacilli usually present and the physical signs are improved or stationary; and lastly, "unimproved" or "progressive," which explains itself. In classification of ultimate results he has, besides the heading "cured," that of "well" for such patients as fulfil all the conditions required under "cured," but about whose sputum no definite information can be obtained. The "arrested," "improved," and "progressive" are defined as in the classification on discharge.

Opium Smokers in the Philippines.—A. S. Rochester describes the experience and the methods used for the cure of the opium habit in Manila. Permanent cures involving the complete loss of appetite for the drug are seldom, if ever, realized and are not expected. Of 206 patients treated, 197 were Chinamen and three were Filipinos. The length of time which they had been victims of the habit averaged seven and one-half years. A striking fact noticed was the abandonment of the Chinese to a very large extent of the pipe for the use of the hypodermic syringe, and another was the general good physical condition of those who confined themselves to the pipe, as compared with that of the users of the hypodermic syringe. The two classes could be recognized at sight. The rapid withdrawal of the opium from the habitual Chinese opium smoker seems to be attended with very little danger and a surprisingly small amount of suffering. His system regulates itself in a comparatively short time to the absence of the drug, and the removal causes very little diarrhea. The hypodermic users of morphine and those who took opium by the mouth were far harder to treat, and the treatment presented nothing new from that employed in other races. The hyoscine substitution treatment was used in a few cases with very unsatisfactory results, and is unqualifiedly condemned by the author.

Respiration in Chorea Minor.—The importance of the respiratory symptoms in chorea is emphasized by W. W. Graves, who believes that their more general recognition will be a decided aid in diagnosis, especially in the milder and atypical forms of the disease. They are best observed with the thorax entirely exposed, the patient in the supine position with the trunk and limbs in position to afford the most complete bodily reaction. The points to which he calls attention are: "1. Irregular breathing, which is probably due to two factors, (a) lessened amplitude in some movements and increased amplitude in others, giving the impression that no two respiratory excursions are equal. (b) Sudden halts or cogs occurring (usually singly) during either inspiration or expiration, and most frequently during the latter. These do not occur in every respiratory movement, but are of frequent occurrence and appear to be due to a sudden arrest of the movement in one phase by the development of an incomplete movement of the opposite phase, but the original movement usually goes on to completion. These cogs render the respiratory movements distinctly jerky and may well be called choreic inspiratory and expiratory cogs. An inspiratory cog occurs most frequently near the end of expiration and an expiratory cog near the end of inspiration. 2. Now and then a sudden deep inspiration occurs, far exceeding in amplitude the usual unequal inspiratory movements and is succeeded by a sudden explosive (forced) expiratory movement, the whole differing essentially from a sighing respiration by its rapidity in its every phase and by the absence of a pause at the end of expiration. 3. Relative decrease in the length of the normal expiratory phases and relative increase in the length of the so-called normal expiratory phase, and distinct pauses are of frequent occurrence at the end of expiration. 4. Sudden changes from abnormal to costal, or from costal to abnormal, breathing occur frequently, both being observed at times in a single respiratory

combination—a mixture of abnormal and costal breathing and the frequent impression of incoordination—a dissociation in the respiratory movements. When 'pure abdominal breathing' occurs in chorea, movements of the whole chest are reduced to a minimum, and when 'pure costal breathing' occurs the upper abdomen remains practically motionless. 5. The respiratory rate is frequently accelerated and occasionally this may be slower than normal." These phenomena may be seen not only in the mildest cases, but may be also noted by palpation and auscultation, and some of them are among the earliest manifestations of the disease, continue prominently during its active stage and are still perceptible after the other usually recognized motor symptoms have disappeared. This, he thinks, indicates not only that actual recovery may be long delayed, but that the recurrences often observed are true relapses. Three case histories with tracings illustrating the respiratory phenomena are given in detail. Graves has not been able to find a single reference to these easily recognized appearances in recent periodical literature and says that no one has hitherto emphasized their significance in diagnosis. He gives a list of over fifty citations from authors who have written on chorea, giving their utterances as regards the implication of the respiratory organs, and holds that, in spite of the evident general lack of attention to these features, the literature itself warrants the conclusion that certain respiratory phenomena are among the most constant signs of the disease. Of course, if the trunk muscles are involved, those of respiration cannot escape, but this only partially explains the conditions—the incoordination, the amplitude variations, the sudden changes of type, etc., call for another explanation. This he finds in assuming that most of them can be accounted for only by an involvement of the respiratory center by the agent causing the disease.

Medical Graduates.—A. L. Benedict gives a statistical study of the supply of doctors in the United States, from which he figures out that with the present tendencies of the output of graduates from medical colleges and the decrease in the profession by death and otherwise, the number of physicians in the country, which was given as 132,000 by the U. S. Census of 1900, will be 154,000 and over in 1910. This, with the estimated increase in population, will give a slightly increased clientele per doctor from 572 to 594. European experience shows that one physician can easily care for 1,000 of general population, and it is scarcely possible, he thinks, that even by continuing to raise the medical standards, coalescing colleges, and discouraging matriculants, the average graduation list can be so much further diminished as merely to keep the profession at its present numerical strength. Should this result be reached, however, the average clientele would be only increased about ten annually, with the expected increase of the general population, and it would be past 1940 before we reach the proportions of doctors to population deemed normal in European conditions. In other words, we are over thirty-five years in advance of the natural requirements, which means not only individual average suffering for the profession, but also a serious economic problem for the country.

Rocky Mountain Spotted Fever.—H. T. Ricketts describes a somewhat pleomorphic bipolar bacillus which is found in enormous numbers in the eggs of infected ticks, and in their salivary glands, ovaries and the alimentary sac. They are absent from similar structures in uninfected ticks. The organisms are so numerous in the eggs that a sufficient quantity could be obtained for satisfactory agglutination tests, which show as a result that the serums of immune animals produce complete agglutination in dilutions as high as 1 to 160, with marked agglutination still at 1 to 200. Normal serums, on the contrary, produce no agglutination. Positive agglutination was also obtained by the use of serums from human patients, although the results were not so striking, perhaps, because of the fact that the serums were several months old. Normal human serum causes agglutination only in dilutions of 1 to 1 and 1 to 10. Taking advantage of the agglutinative power of immune serums, Ricketts concentrated the bacilli in the serum of freshly infected guinea pigs, subsequently centrifugating the clumps, which were recognized after being fixed and stained with Giemsa's stain. He apparently is convinced that the evidence indicates a specific relationship between this organism and Rocky Mountain spotted fever.

The Lancet, January 23, 1909.

Intestinal Indigestion.—After a general description of this affection, P. J. Cammidge says that its early recognition and treatment are primarily important because of the discomfort the condition causes the patient and also because the interference with nutrition that it brings about but the complications and sequelæ that are liable to occur in chronic cases are of no less moment. Toxemia may entirely unfit the patient for any occupation involving mental strain or concentration and one finds that a considerable number drift into that somewhat heterogeneous group of cases provisionally labeled "neurasthenia." A remote consequence of chronic intestinal indigestion, in the author's view, is the ultimate occurrence of diabetes. This is apparently due to the involvement of the pancreas in the disease, and although at present we do not know with certainty why some cases of chronic pancreatitis, due to infection of the ducts, should develop glycosuria while other and apparently quite similar cases do not, the fact remains that it is not a negligible possibility. The progress of the disease is usually slow, and in some diabetics the symptoms of intestinal indigestion have antedated the glycosuria by fifteen years. The author strongly insists on the prophylactic treatment of diabetes, and to this end the early care of disturbances in the chemistry and bacteriology of the large intestine largely contributes.

Endemic Funiculitis.—D. K. Coutts refers to the incidence of this disease (cellulitis of the spermatic cord) in Egypt where he saw ten cases and was able to follow up five, the histories of which are here given. Frequent reference is made to articles previously published in the *Lancet*. The author thinks that the disease is caused by thrombosis of the pampiniform plexus, due, in turn, to inflammatory changes in the vas deferens. All the author's cases have a history of urethritis which is extremely common in Egypt, but the sequelæ of which are much less severe and of much less significance than in Western European countries. In the acute cases, the onset is quick, but in the milder cases it is more gradual. A swelling is noted in the inguinal region, which increases in size and becomes swollen and painful. The temperature rises rapidly, and unless surgical intervention occurs, the case assumes the acute type. In some cases the affected tissues may be completely excised. In others, the inflamed mass is exposed through the skin and external oblique muscles and is then freely incised. The wound is left open and fomentations are applied every four hours till the surface is cleaned. Orchidectomy seems rarely called for. In the radical operation it is not always easy to decide when the whole of the infected tissue has been removed. In tying the cord high up in the internal ring, an infected focus may be left behind in the apparently healthy stump and cause considerable trouble in the extraperitoneal tissues, below the reconstructed inguinal canal.

Infantile Splenic Anemia.—W. K. Hunter gives extensive clinical notes on ten cases and presents much tabulated material which must be consulted in the original. He refers to three clinical types of the disease, the chief point of distinction between them being the degree of leucocytosis that may happen to be present. In the first type the blood picture is much the same as in splenic anemia of the adult, that is, the white cells are diminished instead of being increased in number and there is most often a lymphocytosis. In the second type the leucopenia is replaced by a moderate leucocytosis, fourteen thousand to twenty thousand per cu. mm. The proportion of the various white cells is little altered, although some myelocytes are to be found in the stained films. This type is more severe than the preceding, and includes most of the cases described under the name of Splenic Anemia of Infants. There is still a third type described (von Jaksch) as pseudoleukemic anemia of infants. Here there is a greater leucocytosis even up to one hundred thousand per cu. mm. Differential counts almost always show a definite proportion of marrow cells and generally there is a greater variety of leucocytes than in normal blood. Most often the lymphocyte predominates, but occasionally the polynuclears. Examination of the red cells in all three types shows nothing distinctive. The causes of the condition are the same as those for ordinary secondary anemia without splenic enlargement. Recovery may occur in the infantile type of the disease.

British Medical Journal, January 9, 1909.

Vincent's Angina.—J. T. C. Nash reports the case of a girl of 20 years with a sore throat. A true case of Vincent's angina had occurred in the house some weeks previously. The girl presented a patch on the right tonsil with mild constitutional symptoms. A swab test revealed the customary fusiform bacilli and spirilla. Recovery followed a week's use of iodine tincture locally and potassium chlorate internally. The author says that in many instances the inhalation of street dust accounts for the sore throat and streptococci and that the Vincent organisms

are merely accidental. He believes that systematic bacteriological tests would reveal them very frequently and hardly regards Vincent's angina as a disorder sufficiently distinct to deserve a specific designation.

Leucocytosis in Appendicitis.—G. Mitchell says that the behavior of the leucocytes in most cases gives a sure index of both the intensity of the local irritant and the patient's power of resistance. A low count signifies a mild case, an abscess thoroughly walled off (Cabot) or a very severe case. When the leucocyte count rises above that indicating pus formation or gangrene and keeps on rising rapidly it shows that a virulent poison is circulating in the system which may gain the upper hand at any moment if operation is not performed. If the general symptoms are severe and the count low death often results. The author recalls two cases of perforated gangrenous appendix with diffuse peritonitis in which the count was 12,000. As to differential count, in the author's cases of acute appendicitis going on to gangrene or pus formation, the percentage of polynuclear cells varied from 70 to 90 per cent. and was generally higher in the gangrene cases than in those of abscess formation. It was also higher in cases presenting evidences of severe toxemia. There is no constant relation between leucocytosis and fever. Several illustrative counts are given. It was noted in operative cases that very soon after the percentage of polynuclear cells and lymphocytes had returned to normal, the percentage of lymphocites became increased.

Appendicostomy, with Notes on the Surgical Aspect of Colitis.—J. B. Dawson recalls the fact that the use of appendicostomy for colitis was preceded by the operations of right inguinal colostomy and cecostomy. The former operation is difficult and the constant flow of fluid irritating feces over the surface of the wound and surrounding skin which becomes excoriated and sore is distressing and requires rest in bed with constant attendance. It is true that by this operation the fecal stream is entirely directed away from the colon, which is thereby given greater rest, but the complete daily evacuation and irrigation possible with appendicostomy seem to be sufficient for the purpose. Cases of colitis have a well-known tendency to relapse, and it is not easy to decide when to close the colostomy wound, for having once closed, the opening is not readily reestablished. With appendicostomy, however, if after treatment has ceased the opening be allowed to stenose naturally, it gives no trouble and at a later date can be dilated with suitable bougies, presence of the mucous membrane presenting complete closure of the fistulous tract. Hence in the author's view cecostomy has been largely superseded by that of appendicostomy. The author notes that the first use of the appendix for irrigation purposes was the result of an unlooked-for incident. Weir was about to perform cecostomy, but in opening the abdomen the appendix presented itself so opportunely that it was utilized instead of the cecum.

Appendicostomy in Diffuse Septic Peritonitis.—W. Billington refers to the Murphy method of treatment which he highly commends and says that he himself has had success in introducing large quantities of fluid into the large bowel by means of the appendix. When the appendix is healthy, as in a perforated gastric ulcer, an incision is made over the lesion and rapid measures are instituted to prevent further contamination. No attempt is made to irrigate or map the peritoneum, but adequate drainage is provided for. Then instead of the usual suprapubic puncture to allow of a rubber tube being passed into Douglas's pouch, a small, vertical incision is made over the lower portion of the right rectus muscle, the fibers of which are separated. The appendix is then pulled into the wound, the distal portion cut off, and the stump fixed in the upper angle of the wound by one or two sutures passed through all its coats and the skin with the surface of which the open mouth of the stump is practically flush. A small catheter is passed into the cecum, while through the lower part of the wound a large catheter is passed down to Douglas's pouch. The patient is placed in the Fowler position and the small catheter connected to a tank of warm saline, which should not be more than three inches above the plane of the cecum.

Berliner klinische Wochenschrift, January 11, 1909.

A Case of Atrophy of the Pancreas.—Keuthe reports the case of a male patient who suffered for several years with recurrent attacks of diarrhea that were often accompanied by glycosuria. Clinical examination of the various digestive functions showed that the stomach and liver functionated properly. On the other hand the administration of a large amount of glucose and of starchy food showed that the tolerance for sugar was markedly diminished; the Cammidge reaction was positive; proteolytic ferment was absent from the feces, the bodies of the meat fibers in the feces were undigested, as shown by their staining reaction, excess of fat was found in the feces. These facts justified the diagnosis of a chronic pancreatitis, malignant disease being excluded by the duration of symptoms and pancreatic cyst being improbable because of the absence of any palpable tumor. The patient died of tuberculosis and the autopsy showed an atrophied pancreas that possessed but the rudiments of pancreatic tissue containing several concretions; a few islands of Langerhans were present, some of them being markedly hypertrophied. Keuthe concludes that the tests employed by him in diagnosing this case are all open to many objections, but the positive result of them all show that an affection of the pancreas may be diagnosed by the careful and thorough use of as many of the recently proposed reactions and tests for pancreatic disease as possible.

Münchener medizinische Wochenschrift, January 12, 1909.

Wassermann's Reaction in Syphilis.—Rolly has examined twenty-five syphilitic patients, seventeen tabetics, and a few persons suffering from hereditary syphilis or from progressive paralysis. He concludes that non-syphilitic patients, even though suffering from such affections as tuberculosis, typhoid fever, etc., do not give a positive reaction in Wassermann's sense. On the other hand, in the cases of syphilitic and parasyphilitic affection, Rolly obtained positive reaction in 95.5 per cent. of the total number. As antigen he used the alcoholic extract of the livers of syphilitic fetuses, and considers that much better results are obtained with this substance than with any other. He warns against the numerous possibilities of error connected with the carrying out of the reaction and names a number of methods by which control experiments may be performed and the various reagents used tested.

The Formation of Concretions.—Schade describes a number of experiments by which he endeavored to learn the conditions favoring the formations of concretions and calculi, as well as the processes that lead to the appearance of these objects in the human body. He concludes that so far as urinary calculi are concerned similar structures may be experimentally produced by the simultaneous precipitation of colloid and crystalline substances. Fibrin may be used as such a colloid, though the formation of calculi succeeds with many other substances of like nature. He claims that urinary calculi are likewise not of crystalline nature alone, but are composed of various colloid substances derived from the urine which form the skeleton of the calculi and about which the salts are deposited. A minimal amount of a colloid substance is enough to act as such a framework, and this explains why only crystalline material seems to form the substance of calculi on superficial examination. The occurrence of soft calculi in which colloid material predominates corroborates the truth of his theory of the formation of calculi. Foreign bodies do not always lead to the formation of calculi; they may be simply incrusted with salts if no reaction has taken place about them. However, the presence of an inflammatory reaction about them may result in the precipitation of more colloid and crystalline substances in that portion of a viscus and then the foreign body may become a nucleus of a calculus. The therapy as well as the prophylaxis of urinary calculi must consider the rôle of colloid substances in the formation of calculi; further study of the conditions favoring the precipitation of these substances should be undertaken in order that diet and remedies may be devised which would oppose the occurrence of such precipitation.

Traveling Needles.—The *Lancet* refers to the curious wanderings of needles through the bodily tissues, and recalls the history of a remarkable case published in its columns some twenty-five years ago. The patient was a healthy Scotch girl, aged 20 years, who had no sign of hysterical tendency but was in the habit of putting pins in her mouth, and sometimes had been known to fall asleep without removing them. She was admitted to hospital, having swallowed five pins accidentally, while fixing clothes, and by the help of emetics she was relieved of them. Returning home, she began regularly to vomit pins and got rid of 23 in the course of a month. She then began to produce needles and in a fortnight 13 came out from the following situations—the left nostril, the origin of the sternomastoid behind the left ear, and a spot on the front of the right forearm, at the same time she continued vomiting pins until 75 had appeared. The needles were blackened and slightly eroded, and two of them were threaded with about three inches of thread.

Book Reviews.

ΙΣΤΟΡΙΑ ΤΩΝ ΗΝΩΜΕΝΩΝ ΠΟΛΙΤΕΙΩΝ ΤΗΣ ΑΜΕΡΙΚΗΣ. Ὑπὸ ΣΟΛΩΝΟΣ Ι. ΒΛΑΣΤΟΥ καὶ ΝΙΚΟΛΑΟΥ ΓΚΟΡΤΖΗ. Ἐν Νέᾳ Υόρκῃ: ἐκ τοῦ Τυπογραφείου τῆς "Ἀτλαντίδος." 1909.

ΑΠΟ ΤΗΣ ΑΚΡΟΠΟΛΕΩΣ ΕΙΣ ΤΗΝ ΑΛΤΙΝ. Ὑπὸ ΣΠΥΡΙΔΩΝΟΣ ΠΑΓΑΝΕΛΗ. Ἐν Νέᾳ Υόρκῃ: ἐκ τοῦ Τυπογραφείου τῆς "Ἀτλαντίδος." 1908.

ΔΥΟ ΕΠΙΤΟΜΑ ΛΕΞΙΚΑ, Ἀγγλοελληνικὸν καὶ Ἑλληναγγλικὸν. μετὰ Προφορᾶς. Ἐν Νέᾳ Υόρκῃ: ἐκ τοῦ Τυπογραφείου τῆς "Ἀτλαντίδος." 1908.

THE publishers of *Atlantis*, a daily Greek newspaper of New York City, in getting out these three books for the Greek inhabitants of this country, have done an unwitting service to all students of Greek. It is an axiom in the study of languages, as in all other acquisition of knowledge, that we should proceed from the known to the unknown, from the easy to the difficult. The study of Latin is much facilitated by a previous knowledge of Italian, and in a much greater degree the difficulties in the way of a comprehension of Ancient Greek are smoothed out for the student by a familiarity with the modern form of the language. As Geldart has said, "Modern Greek is simply Ancient Greek made easy." If one who aims to acquire a knowledge of classical Greek will first set himself to learn the modern form of the language, he will spare himself time and drudgery, and will reach his goal more rapidly than if he began with a grammar of ancient Greek and the reading of Homer or even Herodotus.

In the study of modern Greek, after a preliminary review of the principles of the language, one can make rapid progress by selecting for his reading the first of these books, "A History of the United States," by Solon J. Vlasto and Nicholas Gortzis, for his familiarity with the subject matter will make the reading easy. After he has read that he can take up the second book, "From the Acropolis to Altis" (Olympia), by Spyridon Paganelis, one of the most highly gifted of modern Greek writers, whose description of Greece and of the ancient landmarks is most entertaining, and couched in almost classical language. The reading of both books will be made easy by the very complete, though concise, Greek-English and English-Greek Dictionary. The books are excellently printed, in clear type on good paper, and can be recommended not only to the student who is beginning the study of Greek, but also to anyone familiar with the classical language who wishes to acquire a knowledge of the slight modifications which Greek has undergone in the centuries following the period of Athens' primacy in literature and art.

ELECTRICAL TREATMENT. By WILFRED HARRIS, M.D., F.R.C.P., Physician to Out-Patients, Physician to the Department for Nervous Diseases, and Lecturer on Neurology, St. Mary's Hospital: Physician to Out-Patients, Hospital for Epilepsy and Paralysis, Maida Vale. Illustrated. "We must take the current when it serves, or lose our ventures." Julius Cæsar, Act iv., Sc. iii. Chicago: W. T. Keener & Co., 1908.

THIS little book is a contribution to the Cassell "Modern Methods of Treatment" series, and for those who use electricity therapeutically in their practice, will be found convenient and practical. Particular attention is given to the work that may be done with a good faradic and galvanic battery. Explanations of the theory of the various forms of current are entered into, however, and those who wish to familiarize themselves with the uses of the "high frequency," or the sinusoidal, or the Leduc current, electric light baths, etc., may therein be enlightened.

COMMON AFFECTIONS OF THE LIVER. By W. HALE WHITE, M.D., F.R.C.P. Senior Physician to and Lecturer on Medicine at Guy's Hospital. New York: William Wood & Company, 1908.

IN response to many requests, the author has recast his clinical lectures on diseases of the liver, and now offers them in book form. What he may have lost in completeness he has more than made up by the incisiveness and personal touch which accompanies his descriptions. The less common affections of the liver he either omits or passes over briefly, concentrating his attention on the ordinary ailments. The contents comprise Hepatoptosis, Jaundice, Diseases of the Vessels and Suppurative Conditions, Cirrhosis, Syphilis, Cancer, Fatty and Waxy Liver, Tuberculosis, Actinomycosis Hydatids, and other cystic conditions. The section on Cirrhosis is particularly helpful and full of useful hints, which are urgently brought out in the manner of the clinical instructor whose business it is to teach and not merely enumerate.

Although the author has designed this work for students, it could well prove most useful to those further advanced, and we believe that very few practitioners could read these lectures without learning something either new or forgotten. The vast experience of the author in the wards and autopsy rooms of Guy's Hospital has enabled him to speak with authority and with well-balanced ideas of the relative importance of signs, symptoms, or treatment. Discarding the irrelevant, and proceeding to the root of the matter is an excellent method of teaching, and the Senior Physician of Guy's shows these traits throughout his excellent little book.

HUMAN FOODS AND THEIR NUTRITIVE VALUE. By HARRY SNYDER, B.S., Professor of Agricultural Chemistry, University of Minnesota, and Chemist of the Minnesota Experiment Station. New York: The Macmillan Company, 1908.

THE book before us was prepared by the author for his classroom at the University of Minnesota. It is practical and concise, and contains much instruction in proportion to its size. The work will prove of great value to physicians who need instruction on dietetics, the physical, chemical, and bacteriological changes occurring in food. The effects of storage, the relative cost and value of food are also considered. Numerous tables, illustrations, formulæ, etc., help to make the book of value as a reference handbook. The rational feeding of man, the various kinds of household waters, the interpretation of water analysis are all important subjects, and receive due notice at the hands of the writer. It is a book of value to both sanitarian and physiological chemist.

MÉDICAMENTS MICROBIENS: BACTÉRIOTHERAPIE VACCINATION SÉROTHÉRAPIE PAR METCHNIKOFF, SACQUÉPÉE, REMLINGER, L. MARTIN, VAILLARD, DOPTER, SALIMBENI, BESREDKA, WASSERMANN, LEBER, DUJARDIN-BEAUMETZ, CALMETTE. Avec 26 figures dans le texte. Paris: Librairie J. B. Baillière et Fils, 1909.

THIS is one of a series of volumes on Therapeutics that is to appear under the general direction of Gilbert and Carnot. As seen from the title, it considers the most recent methods of therapy, and consists of a series of special articles written by men who have done original work in the subject considered. Metchnikoff's contribution deals with intestinal bacteriotherapy, and states the well-known views of the author in regard to the rôle of the bacterial flora of the intestines in health and in disease; Wassermann and Leber write of serum treatment of epidemic meningitis; Calmette considers the treatment of snake bites; the other authors consider vaccination, the treatment of rabies, the prevention and specific treatment of typhoid fever, of infection with the streptococcus, of bubonic plague, of Asiatic cholera, of diphtheria, and of tetanus. It is hardly necessary to recommend this book to the attention of physicians because the subject of it is of such daily importance, both to the practical worker and to the scientist, that the mere title with the list of collaborators is enough to attract the attention of the progressive physician. The volume saves a great deal of hunting through recent literature, the latest work in the subject being presented by the authors of the various articles. It gives an authoritative picture of the success that has attended the introduction of vaccination and of serotherapeutic procedures into the treatment of disease and at the same time shows the limitations of such therapy and the problems that still await solution.

THE ART OF NATURAL SLEEP. With definite directions for the wholesome cure of sleeplessness, illustrated by cases treated at Northampton and elsewhere. By LYMAN P. POWELL, Rector of St. John's Church, Northampton, Mass. Author of "Christian Science: Its Faith and Its Founder"; Editor of "Historic Towns of the United States." G. P. Putnam's Sons, New York and London: The Knickerbocker Press, 1908.

THIS little book is likely to become one of the "official books" of the so-called "Emmanuel Movement." Like some other similar books, it is doubtless a protest in part against the ultraconservatism of the medical profession toward the legitimate employment of hypnotic suggestion in the treatment of certain nervous disorders in their practice. The American neurologist is constantly complaining that his field is so much encroached upon. His European confrère is less conservative in this respect and therefore less harassed. This book, written by a layman, contains nothing new from a medical standpoint. Injected throughout, however, is the principle on which the Emmanuel movement mainly relies, viz., faith. This is "first reinforced by heterosuggestion and then by patient and persistent autosuggestion." Verily, is there not "something in it?" The author contemplates a treatise on the suggestive treatment of other nervous disorders.

Society Reports.

WESTERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Eighteenth Annual Meeting, Held at Minneapolis, Minn., December 29 and 30, 1908.

THE PRESIDENT, DR. W. W. GRANT OF DENVER, COLO., IN THE CHAIR

Value of Enterostomy in Intestinal Obstruction.—Dr. JOHN P. LORD of Omaha, Neb., said that the general mortality after operation for intestinal obstruction was probably from fifty to eighty per cent. According to Elsberg, in only about ten to fifteen per cent. of cases entering Mount Sinai Hospital, New York, was the condition still to be considered a good one; and fifty-four died out of one hundred cases entering three of the large hospitals in New York during 1906. The extreme conditions commonly met with required too much anesthetic, too much surgery, and too much time for successful surgical relief by radical intervention. Until earlier diagnoses were made enterostomy should be done to drain the toxic contents of the intestinal tube and stop the absorption of the ptomains. This relieved conditions which, if allowed to continue, became rapidly fatal. It met the indications without necessarily killing those who were extremely ill. It was not a last resort, to be withheld from those who were in good or fair condition. Inanition, formerly feared, skin excoriation, and the necessity for a secondary operation, were all eliminated by the present methods. Liquid nourishment, stimulants, and cathartics might be administered with most valuable results. Irrigation and drainage and the use of the Moynihan tube, now considered so valuable, might also be accomplished before the wound was closed, and might also be used to a limited extent afterwards. The necessity for a radical secondary operation was sometimes obviated by this "tide-over" procedure, because of the subsidence of peritonitis, the consequent infiltration, the paralysis, and even the angulation which was due to overdistention. The author reported four successive, but successful, cases to illustrate the results of enterostomy in acute post-operative obstruction.

Dr. WILLIAM D. HAGGARD of Nashville, Tenn., thought the lesson of this paper should be heeded. There was not a surgeon who had not had the mortifying experience of a tremendously high mortality attending the hopelessly delayed cases of intestinal obstruction. If we could operate on these cases quickly under local anesthesia by enterostomy, he had no doubt we would be able to save a much larger proportion of them primarily.

Dr. J. F. PERCY of Galesburg, Ill., said that in 1902 he opened the abdomen of a doctor's son for delayed appendicitis. He did it at the request of the young man, and found therein a condition that was embraced in the title of Dr. Lord's paper, where everything was black, and he recognized that there was something besides opening the abdomen for drainage to be done in the care and cure of these patients. His next patient, about a year afterwards, was brought into the hospital cyanotic and in a moribund condition. He directed the anesthetist to put cold water on the mask because the man was near dead, and he wanted one or two members of the family in the room, so that if the patient died on the table there would not be any question as to responsibility on part of the operator. He made a quick opening in the right iliac region and grasped the first piece of intestine that presented, fastened it, and opened it. The patient remained in a semiconscious condition for three weeks, but made an operative recovery. Some two or three months afterwards, when he got tired of the fistula he had, Dr. Percy opened him up and resected about sixteen or eighteen inches of the gut, after which the patient made a perfect recovery. He had had three similar cases, this one making four in all, since 1903, and all of them had recovered by that treatment.

Dr. R. C. COFFEY of Portland, Ore., said that the mortality from intestinal obstruction was doubtless fifty per cent. less than it was two years ago. This lowered mortality rate was due to two or three things. First, the family physician recognized now that acute distention of the abdomen, which could not be accounted for in any other way, was to be looked upon with grave suspicion. Second, we had learned that a paralyzed bowel, distended, in which there were ecchymotic spots developed on the intestine above, was dangerous, and it would not empty itself, even though the constriction was relieved. Finally, one of the most important things in dealing with these cases of intestinal obstruction was to keep out everything from the stomach that was possible, in order to prevent the formation of gas.

Dr. F. GREGORY CONNELL of Oshkosh, Wis., said that there could be no question as to the advisability of performing enterostomy in severe cases of intestinal obstruction, and he did not think any one would doubt the inadvisability of doing this operation in the early or mild case. If we did enterostomies unnecessarily, the mortality rate would be higher than was necessary. This point should be emphasized. In cases of acute intestinal obstruction the necessity of infiltration anesthesia should be used.

Dr. JAMES E. MOORE of Minneapolis asked when one should do enterostomy, and when a radical operation in these cases of acute intestinal obstruction? He thought it would be equally objectionable to undertake to do a radical operation in all these cases as to do enterostomy in all cases, because a fecal fistula was a very uncomfortable thing for the patient, and it did not enhance the reputation of the surgeon. It would necessitate an operation later, which was not free from danger.

Dr. FREDERICK A. DUNSMOOR of Minneapolis reported the case of a girl who had been operated on three times for obstruction of the bowels. He operated on her a year ago for an acute appendicitis from which she made a good recovery. Six months later she was operated on again by a colleague in his absence for acute intestinal obstruction, which was relieved. Later, while skating, she was seized with pain, and was operated on, the operation disclosing obstruction at the upper part of the ileum, and by liberating bands and separating adhesions he was enabled to establish perfect patency of the intestinal tract. Two weeks later he was called to see the girl again for obstruction of the bowels, with enormous dilatation of the entire small intestine. The intestine was filled with the same kind of fluid that had been described in cases of acute dilatation of the stomach. There were three quarts of this black fluid, which was largely made up of bloody substance at the time. He succeeded in establishing normal patency of the bowel, and while the patient was not in the very best of condition at the present time, she was still alive. She had a fistula.

Dr. A. L. WRIGHT of Carroll, Ia., spoke from the standpoint of a patient. In March he had his first attack of appendicitis. Within eight hours from the onset the appendix had ruptured, and it was removed within fifteen hours from the onset of the first symptoms of any trouble in his right flank. Following the operation he had septic ileus, and for four or five days suffered intensely. The abdomen had been packed open, but not until a ligature was placed about the appendix for closure did he get relief, which was prompt. He wished, therefore, as a recent sufferer, to urge opening up the bowel (if the patient was in such a condition that further operative interference was unwarranted) by using sharp-pointed scissors, and giving vent to the contents, as he thought by so

doing we would save a much larger percentage of these patients.

Dr. Clifford U. Collins of Peoria, Ill., said the remarks of Dr. Connell raised the question in his mind with regard to the drowning of these patients in the fecal vomit. A few years ago, when Dr. E. Wyllys Andrews published his paper, he saw a case in which the material which came from the mouth of the patient was greatly in excess of any quantity that could be contained in the stomach. Probably under the influence of the anesthetic the pylorus became relaxed and a vast quantity of material was forced into the stomach by the combined pressure below. If that was the case, it occurred to him that washing out of the stomach as a preliminary to anesthesia would prevent that trouble. Since then he had operated on patients in the reverse Trendelenburg position, allowing gravity to keep the intestinal contents from escaping, and so far that trouble had been obviated.

Dr. Van Buren Knott of Sioux City, Ia., said that enterostomy had lowered the mortality from intestinal obstruction, but it had by no means eliminated it. From the general trend of the discussion it would seem that enterostomy in these cases, no matter how late it was done, in the hands of a good surgeon, was a life-saving procedure. This was by no means his experience. He had had many cases in which enterostomy had been done, yet the patients had gone on and died just the same. Multiple enterostomy with drainage had proven valuable in his hands.

Abscess of the Brain.—Dr. W. H. Magie of Duluth, Minn., reported two cases of brain abscess in detail and made a plea for a more thorough and systematic exploration of the brain in suspected cases. He was satisfied that, as a rule, the surgeon of ordinary experience was too timid in his exploration of the brain in suspected abscess. These cases were absolutely hopeless unless the abscess was located and drained. Knowing this to be the fact, we were justified in undertaking almost any operative procedure in our efforts to locate and drain such abscesses.

Indications for Obliterative in Contradistinction to Reconstructive Endoaneurysmorrhaphy.—Dr. W. J. Frick of Kansas City, Mo., believed that in the vast majority of cases the radical obliterative endoaneurysmorrhapy was the operation to be preferred, for the following reasons: 1. The procedure was definite, thorough, and radical. 2. No plastic work in diseased tissue was required, such work being notoriously uncertain. 3. In a majority of cases the sac configuration and intrasaccular conditions would preclude plastic work. 4. In reported cases, where apparently either method might have been employed equally well, the obliterative method had been more satisfactory and had shown greater freedom from untoward sequelæ, such as recurrence, hemorrhage, thrombosis, gangrene, etc. 5. A pathological aneurysm was a malignant degeneration in a vital structure. The diseased vessel could no longer be depended on and deserved obliteration. The author reported two cases, one the saccular type of aneurysm, the other a large popliteal aneurysm of nine months' duration, on which he had operated, with recovery in both instances. The technique of intraaneurysmal surgery resolved itself into several distinct essential steps: 1. Preliminary hemostasis. To accomplish this was more or less difficult, according to the situation of the aneurysm. Esmarch compression of the main artery above, and temporary, direct compression above and below were variously used. A bloodless field was almost a *sine qua non*. 2. Free opening of the aneurysmal cavity to permit a careful survey of the interior of the sac before deciding on the plan of procedure. 3. Intrasaccular suture of orifices. 4. Obliteration of cavity by sutures. 5. Closure and drainage. The after-treatment of these cases was usually simple, only one or two points being worthy of comment. The part operated on was best immobilized by some suitable fixed dressing in a position of relaxation. This prevented tension on the vessel wall longitudinally, and also allowed free play for the establishment of a collateral circulation. Drainage should be removed early, as soon as its purpose was served.

Dr. John P. Lord of Omaha was greatly interested in the work of Matas from the first, as well as in the work done by others, and had been looking for cases that were suitable for the Matas procedure. He had had two cases of popliteal aneurysm, but when he came to consider the feasibility of treatment by this method, and began to look up the subject, he found that both of these cases were poor subjects for surgical exploitation. The arteries were generally sclerosed; the arterial tension was high, while the kidneys were not in a good condition. One of his patients was a man, 60 years of age. When one looked over the literature he became impressed with the wisdom of John Hunter and the value of his procedure of litigation of the femoral artery. He was likewise impressed with its simplicity and how easily the operation was borne by the patient. Dr. Lord resorted to litigation in both of his cases; the patients did well, made good recoveries, and were still alive. He was not fully convinced of the advantage of doing aneurysmorrhaphy in all cases of popliteal aneurysm. It did not appeal to him.

Subserous Appendectomy.—Dr. E. M. Sala of Rock Island, Ill., reported four cases in which he resorted to the removal of the appendix, except its serous coat, thus avoidin gdisturbing adhesions of the appendix to other viscera. He believed the method had a permanent place in surgery and was the operation of choice in certain forms of adherent appendix. 1. The vermiform appendix might be shelled out of its peritoneal covering or serous coat. 2. The remaining serous coat could not cause a recurrence. 3. This method of dealing with an appendix, which was glued to other important structures, avoided the disagreeable sequences of loosening up strong adhesions, and in many cases might preclude subsequent operations, which were always embarrassing to the operator, and a misfortune to patients.

Dr. John P. Lord of Omaha had availed himself of this procedure in suitable cases, and was reminded of one patient upon whom he operated eight years ago, following a technique similar to the one that had been described by Dr. Sala. In this case a young surgeon had worked for an hour and a half in trying to deliver the appendix, but by this means the speaker was enabled to deliver it from the bottom of the pelvis. This procedure was valuable, in that it saved much trouble and lessened danger.

Chronic Dilatation and Prolapse of the Stomach.—Dr Arthur E. Benjamin of Minneapolis said that the disease known as dilatation of the stomach was now engaging the attention of the medical and surgical world. The association and relative importance of stomach prolapse was also being recognized. Recent investigations had demonstrated that reported deaths due to heart failure, gastralgia, acute indigestion, etc., might have been in some instances due to acute dilatation of the stomach. His conclusions were that: 1. Chronic dilatation and prolapse of the stomach were often interdependent and associated. 2. As possible antecedents of an acute dilatation they must be recognized. 3. As factors in the causation of ulcers or cancer they should be considered. 4. The causes for dilatation and prolapse might be similar and primarily were often due to indiscretion in diet, followed by weakened gastric support, motor insufficiency, or partial obstruction. 5. The exact nature and variety of the ptosis or the dilatation should be determined, if possible, by *x*-ray and other means. 6. Symptoms actually due to chronic dilatation or prolapse were frequently termed hysteria, neurasthenia, or nervous dyspepsia. 7. Acute upper abdominal pain or attacks of vomiting were often misinterpreted; they were frequently due to acute pyloric or duodenal obstruction and gastric disten-

sion. 8. Hyperchlorhydria, post-operative vomiting and vomiting of pregnancy might be dependent upon the presence of chronic dilatation or prolapse of the stomach. 9. The treatment should depend on the conditions found. 10. Simple cases were often amenable to medical and mechanical means, such as diet, exercise, mechanical support, hygiene, etc. 11. Certain cases should be operated on, especially those of actual pyloric or duodenal obstruction or of the sagging type, and other aggravated cases not relieved by medical means. 12. Some cases were dependent on an associated visceroptosis and relaxed abdominal walls. These should be properly treated to bring about the relief dependent on such a general prolapse. 13. In the sagging types the Beyea operation, whether alone or supplemented by the Coffey operation, if there was an associated sagging of the transverse colon should be done. 14. Chronic dilatation of the stomach not dependent on obstruction and when not otherwise relieved was greatly benefited and often cured by the Bircher operation of plication. 15. In chronic dilatation, dependent on a benign pyloric obstruction, a short loop gastroenterostomy should be performed. 16. Obstruction or dilatation dependent on malignant growths might call for a pylorectomy. 17. In operating a careful search should be made for any other points of chronic bowel obstruction, as from disease of the gall-bladder, appendix, or from a kinking colon, etc. These conditions might add to digestive disturbances and should be corrected at the same time. 18. All cases operated upon should be followed for some time and the subsequent treatment carefully managed.

The Surgical Importance of the Intestinal Gases.—Dr. B. B. Davis of Omaha said the points that practical surgeons needed especially to have in mind were: (1) To have as little fermentable substance as possible in the intestines before operation. (2) To do as little as possible during the operation, which would interfere with the normal circulation in the intestinal wall. This could probably best be prevented by a minimum amount of handling and resulting trauma. (3) To leave the intestines in the best condition for active peristalsis. Long exposure and much cooling were inimical to active peristalsis.

Dr. D. S. Fairchild of Des Moines, Ia., read a paper in which he discussed post-operative acute dilatation of the stomach.

Dr. R. C. Coffey of Portland, Oregon, said there were able men who considered prolapse of the stomach a non-surgical condition, while there were others who believed that it was a surgical condition under practically all circumstances. From the experience he had had in this work, he should say there was a happy medium. Not more than twenty-five per cent. of the cases of prolapse of the stomach, as seen by the internist, had any surgical features. Probably not more than one in five had any surgical features, but the fact remained a certain number of them did have surgical features and the results of surgical treatment were practically as good as in gastric ulcer.

Dr. Daniel N. Eisendrath of Chicago said that during the past few years at the Michael Reese Hospital, Chicago, they had paid special attention to acute cases of dilatation of the stomach in order to determine the cause of some of them. They had found in quite a large proportion of cases that the direct cause of the acute dilatation of the stomach was repeated capillary hemorrhages, and had substantiated this by examinations of the washed contents of the organ and by other tests, showing that the hyperacid contents were bloody. There was no hematemesis in the sense that we get it from a gastric ulcer or from gall-stone complications.

Dr. Charles H. Mayo of Rochester, Minn., said that if the internist picked out one case in twenty-five and sent it to the surgeon, he would probably operate on one in five, which would be one in 125 that presented symptoms. If the stomach got larger and was able to do its work and to empty itself, it was probably not [illegible] surgical condition. If one could find the pylorus open, and there was no kinking of it, operation might not be called for.

Dr. Jabez N. Jackson of Kansas City, Mo., said that some years ago he had two unfortunate experiences. In each instance the patient belonged to that class of people in whom there was a marked disturbance of metabolism previous to operation, as evidenced by a change in the color of the skin, flabbiness of the complexion, and general laxity of the tissues. These patients consumed an unusual amount of the anesthetic. He had, therefore, come to believe that probably the primary cause in most cases was a disturbance of the metabolism which was increased as the result of the toxic influence of the excess of anesthetic. In recent years, since the open method of administering ether had been adopted, and the giving of it in small quantities, this trouble had disappeared.

Dr. J. W. Andrews of Mankato, Minn., was reminded of the case of a woman, past middle age, with malignant kidney of sufficient size to bulge forward to a considerable extent, and he removed it through the peritoneal cavity. The patient did well for about ten days, then acute dilatation of the stomach occurred, beginning with vomiting of coffee-ground material. The patient died, and at the post-mortem examination he found the largest dilated stomach he had ever seen. It was so enormously dilated that it reached down to the brim of the pelvis. During the past year a severe epidemic of typhoid fever occurred in his region, and there were several cases of acute dilatation of the stomach accompanying the typhoid. In these typhoid patients the stomach was greatly dilated; but the intestines were no more distended than was usually the case in typhoid fever, yet every one of those patients died from acute dilatation of the stomach. Whether this was due to the capillary hemorrhages spoken of or not he did not know. At any rate, it was an extremely fatal condition.

The President asked if the stomach was washed out.

Dr. Andrews replied that they did not wash out the stomach in the typhoid cases.

Dr. M. L. Harris of Chicago said that he had come to classify the cases of chronic dilatation of the stomach under two heads: those in which there was mechanical obstruction and where surgical interference was the proper treatment, and those in which there was no mechanical obstruction. It was doubtful, in his mind, whether the latter were benefited by operative measures. He had never seen any good reason for the plication of a dilated stomach. If a stomach was dilated as the result of mechanical obstruction, plication was useless. If it was not dilated from mechanical obstruction, but from atony or any other condition, the plication would interfere with vermicular action. He had never seen the rationale of plication of the stomach.

Dr. Henry T. Byford of Chicago said that a dilated stomach was different from a normal stomach. If one plicated the normal intestine, for instance, it would interfere with its function, and if the stomach was plicated it would interfere with its contraction. There was a pouch, it hung down, and would not relieve itself, and we could not very well, if it was a surgical case, diminish the contractile power of the stomach. In such a case, if we could bunch it up, relieve the pouch, help drainage through the duodenum, and help the physical condition, we were establishing temporarily postural treatment, thus giving the stomach a chance to empty itself, and as probably the adhesions would stretch after a while, we had not injured the stomach; we had not injured motility which did not exist.

Diagnosis in Its Relation to the Laboratory and the Bedside.—Dr. W. W. Grant of Denver selected this title for his presidential address, and, among other things, said that a detailed critical study of the history of cases and of the meaning of clinical signs, subjective and objective, was, he feared, not the common practice, even of sur-

geons. There was too much reliance, even when not necessarily exclusive, placed upon instruments of scientific precision and upon laboratory diagnoses, and too little upon the training and discipline of one's own faculties in his accustomed work. The result was a few expert diagnosticians in certain departments, and a general decadence in diagnostic skill and acumen. Sound judgment in the many phases of our work was the growth of natural fitness, education, close observation, and the knowledge of laws and facts governing specific and general diseases. A great surgeon was not a mere mechanic; he was as well a good physician and a trained clinician. Science was not the exclusive property of the expert nor the necessary product of the laboratory. The aim should be not to produce fewer experts in research work, but more scientific clinical experts and diagnosticians. This was necessary to the broader culture and usefulness of the profession, as well as to the best welfare of the sick. Surgery as a study was not exclusive, although its practice might be. A narrower view of the subject was not conducive to the best education, nor to the most thorough equipment. The personal equation was of the greatest moment; but great surgeons were not made by imitation, and skill in diagnosis was a protean product that could never be measured by the rod and the plumb.

Sarcoma of the Fibula.—Dr. J. Clark Stewart of Minneapolis read a paper on this subject which was based upon two cases observed within one month. The tumor was quite rare, though probably not so rare as the study of the literature would show, as many cases were not reported. The trend of the best modern practice seemed to lean toward the less severe operation followed by the Coley treatment, rather than the classical high amputation or disarticulation. The histological type of sarcoma seen before dissemination determined the result. The softer periosteal sarcomata, as well as their prototypes in the central groups, after they had penetrated the bone and invaded the soft parts, were probably never cured by operation, and only rarely by the Coley treatment, while giant and large spindle-cell tumors were of slow growth and slow to form metastases, and thus made possible better results and permitted of conservative operations. He thought that every case of inoperable sarcoma and every case of sarcoma after operation should be given the Coley injection treatment, as the successes of this method had been too numerous and striking to justify anyone in not giving his patient what was certainly a fighting chance for his life.

Dr. James E. Moore of Minneapolis thought that conservative operations were the proper ones. Patients who were to be saved by operation could be saved by a conservative operation, and those cases of the most malignant type were not saved by extreme operation, so that it was proper and right to remove the bone involved or part of it at times and take the chance.

Dr. J. W. Andrews of Mankato, Minn., said that a few years ago he had a case similar to the one reported. In this case the sarcoma occurred at the distal end of the fibula and involved one-third or possibly one-half of the bone. He recommended the removal of the fibula; but the patient went to Rochester, where amputation above the knee was recommended. She was not willing to submit to that operation, returned, and concluded to take the speaker's advice of excision of the entire fibula. This operation was performed by him, and she made a beautiful recovery.

Dr. B. B. Davis of Omaha said that of the cases of sarcoma he had seen, he had observed a number of them which involved the tibia, but only one of the fibula.

Dr. Jabez N. Jackson of Kansas City, Mo., reported a case of sarcoma of the upper end of the fibula which was treated by operation, but recurrence took place in less than a year after operation at the site of the original tumor.

Treatment of Tetanus.—Dr. William Hessert of Chicago said the best treatment of tetanus was to prevent the disease by prophylactic injections of antitetanic serum. He summarized the treatment of tetanus as follows: (1) General accepted methods of local wound treatment should include the use of peroxide of hydrogen and balsam of Peru. (2) The serum treatment should be limited to subcutaneous injections, at least 1,500 units, twice daily, and continued for days and weeks, as the case demanded. (3) Injections of 25 per cent. magnesium sulphate solution by lumbar puncture, exercising great care, especially with the initial dose and in the case of children. The patients should be in a sitting posture and the injection repeated as often as necessary. Its toxic effect on the medulla should be watched for, as shown by depression of the heart and respiration. (4) Proctoclysis was a valuable adjunct. Much depended on good nursing, with proper food and stimulation. Chloral and bromides could also be given, if there was no contraindication.

Dr. M. L. Harris of Chicago thought that when tetanus had once developed antitoxin was practically useless, and our hope must be centered entirely on the injection of some substance or agent which would control the spasms of the patient long enough to permit the system to break up the combination of the toxins in the body and eliminate them. So far, the best treatment seemed to be injections of sulphate of magnesia. He had used it in three cases, two of which recovered and one died.

Dr. Daniel N. Eisendrath of Chicago said that every punctured or blank cartridge wound ought to be converted into an open wound, and the only way to treat these cases, no matter whether the wound or wounds were in the hand or foot, was to anesthetize the patients, put on an Esmarch constrictor, open up the wound from one end to the other, and cut away all necrotic tissue, taking away the pabulum for the bacteria to develop there.

Dr. F. Gregory Connell of Oshkosh reported two cases of tetanus in which he injected magnesium sulphate into the spinal canal, but both patients died.

Dr. Roger B. Brewster of Kansas City, Mo., said that he had had two cases under observation recently. These occurred in the practice of Dr. Geo. M. Gray. One was a boy with a wound of the hand. His jaws were locked. He was given antitetanic serum, the wound was thoroughly cared for, he was put on potassium bromide, and recovered. The other case was a young man, 21 years of age, with a wound of the index finger. Dr. Hertzler amputated the finger; gave him antitetanic serum; put the patient on 20-grain doses of potassium bromide every four hours, and kept him under that for about ten days. It was ten days before trismus was relieved. His spinal and neck muscles were all set, as well as abdominal muscles, but on the tenth day he was relieved, and from that time made a good recovery.

Dr. Mayo said that the incubation period was the main thing in considering these cases. If we took the cases of tetanus that began within seven or eight days, we lost eighty per cent. of them, whereas of those cases that did not begin until after the tenth or twelfth day, we would save eighty per cent. of them.

Dr. W. D. Haines of Cincinnati said prevention of tetanus was the *sine qua non* of treatment, and after they had introduced an ordinance in Cincinnati doing away with the toy pistol and the cannon cracker, they had not had a death the first year.

Technique of Cleft Palate and Hare-lip Operations.—Dr. Joseph Rilus Eastman of Indianapolis said that Lane, who declared the best time for cleft palate operations to be the day after birth, or as soon thereafter as possible, and whose position at first seemed open to criticism, had many followers. Many operators had expressed an assured conviction that the newborn child bore surgery much

better than had been imagined. In ordinary cleft palate operations, during the first week, the loss of blood should be trivial, but however this might be, the danger from loss of blood was not greater than at a later period. Experience had not suggested the slightest foundation for the truth of the statement that young infants did not bear the loss of blood well. There was no reliable evidence to the effect that a very young infant did not bear the loss of a given proportion of its blood as well as an older individual. In denuding the margins of an incomplete palate cleft, the strip of mucous membrane should be removed, if possible, from the entire edge in one piece, in order that the denudation might be complete all around. If the two sides of the cleft were denuded separately, there was considerable likelihood that a small piece of mucosa might be left at the apex, interfering with union at a critical spot. Denudation should begin at the tip of the uvular half upon one side and continue all around the edge of the cleft, finishing at the tip of the opposite half of the uvula. In cutting off the strip the knife should be so held that more membrane was cut from the nasal than from the oral side of the palate. This facilitated coaptation with mattress sutures. In cases of narrow cleft combined with high palatal arch, it was often not difficult to coapt the edges with mattress sutures after the separation of the muco-periosteum from the hard palate with Brophy's periosteotome or dentists' scalers curved at right angles on the flat. In cases of high palatal arch, if the cleft was not too wide, it was sometimes unnecessary to make incisions for the relief of tension, for after separation the two flaps would fall together, like the two halves of a cantilever drawbridge, and might be sutured without tension. The soft palate must be quite completely separated from the hard palate at the posterior border of the latter, as emphasized by Barry. In order to avoid the occurrence of a notch on the lip after the wound had shrunken, the following practice might be followed: After freshening was done, according to one of the well-known methods suitable in the case, and after introducing the horsehair sutures, a little roll of gauze about the size of the distal phalanx of one's little finger was fixed with its long axis transversely to the plane of suture, and the long ends of the upper most and lowest horsehair sutures were tied over the little gauze roll, so that the line of suture was wrapped, so to speak, around the gauze for about two-thirds of its circumference. This simple plan would effectively prevent notching after healing was completed, and, moreover, it kept the dressings in place and by gently stretching the wound margins maintained coaptation.

Plastic Surgery of the Abdominal Wall.—Dr. Robert C. Coffey of Portland, Ore., defined abdominal hernia as a protrusion of the abdominal contents through the abdominal wall proper, or beyond the ordinary plane of the abdominal wall; therefore either an absolute hernia in which the contents passed through an actual opening in the fascial wall—inguinal, femoral, umbilical, and post-operative or traumatic—or relative, in which a certain portion of the abdominal wall of fascia was weakened to such an extent as to allow protrusion of the contents of the abdomen without an actual opening in the fascial wall. Another form of relative hernia was manifested by an increase in distance and protrusion between the umbilicus and the anterior superior spinous process of the ilium, due to transverse stretching of the fascia of the external oblique. This condition might be unilateral or bilateral. This condition was treated as follows: Split the fascia of the external oblique parallel to the fibers in such a manner as to converge with a like split on the opposite side at a point just above the symphysis pubis. Separate the fascia from the internal oblique. Draw one layer of fascia under the other with quilt sutures of linen, taking care to have the loop of thread include the fibers of fascia in a transverse direction. Suture the remaining free edge of fascia to the outer surface of other layer with a continuous catgut suture to further improve apposition at the free edge. Thus the distance between the umbilicus and anterior superior spinous process had been diminished, the protrusion had been reduced, and the fascial wall had been doubled. The result was an abdominal supporter made of the patient's own tissues, and might therefore be termed an autoplastic bandage. Two cases treated by this method, one unilateral and one bilateral, had been entirely successful. The one was performed eighteen months ago, and the other eight months ago.

Surgical Types of Abdominal Tuberculosis.—Dr. William D. Haggard of Nashville, Tenn., said that after the lungs and bones, the intestines, pelvic organs, and peritoneum were the strongholds of tuberculosis. The duodenum and esophagus seemed practically immune, due to the rapid passage of the contents of these tubes, which allowed no opportunity for microbic fixation. The stomach immunity was due to the destructive action of the gastric juice on the tubercle bacilli. There were nine instances of primary tuberculosis in the literature, and 57 cases of secondary involvement of the stomach. The small intestines were involved secondarily, usually, but it occurred primarily oftener than was formerly believed. About 25 per cent. of tuberculosis was said to gain entrance into the system through the intestinal mucosa. It was a disorder of child-life, due most probably to infected cow's milk. It attacked lymphoid tissue, which abounded in the lower ileum. Stagnation invited bacterial entrance. Intermittent pain and diarrhea were the chief symptoms. Strictures and peritonitis were the principal sequelæ. Nearly half of the cases of intestinal stenosis were caused by tuberculosis. It was marked by chronic obstruction and the "ladder-like" appearance of the abdomen. Resection or short-circuiting was indicated. Eighty-five per cent. of abdominal tuberculosis occurred in the ileocecal region. Swallowed bacilli were causative. Chronic obstruction sometimes resulted. Clinical examples, with operative records of the author, were reported. Hyperplastic tuberculosis of the cecum, with perpendicular induration in the right flank, was fatal without excision or other surgical measures. Illustrative cases were cited. Mixed infection resulting in abscess from ileocecal disease was also illustrated by two operative cases, with recovery. A case of tuberculosis of the omentum adherent in a hernial sac of a boy, requiring removal of almost the entire omentum and the appendix, was narrated. Tuberculosis of the appendix, apart from the cecum, was comparatively rare. Chronic peritonitis with ascites was usually tuberculous. The Fallopian tubes accounted for greater prevalence in women. From 7 to 17 per cent. of all tubes removed were tuberculous. Simple laparotomy cured only those cases of the ascitic variety in which the tube became adherent and the tuberculous process became thus obliterated. Recurrent cases required the removal of the focus of disease in the tubes for permanent cure. The ulcerative and fibrous types were unsuited to operation. The suppurative form was usually fatal in spite of operation.

Repair of the Internal Ring in Oblique Inguinal Hernia.—Dr. F. Gregory Connell of Oshkosh, Wis., divided the methods of radical cure of oblique inguinal hernia into two unequal divisions. (1) In which the result was an anatomical reproduction of the normal relations. (2) In which the resulting relations were markedly different from the normal. In class one all the relations were, as a rule, reproduced except that of the internal ring in the transversalis fascia, which was usually allowed to remain in a dilated condition, or was sutured from above downward, which resulted in an abnormal descent of the ring, with consequently a shorter and less oblique canal

In order to reproduce the normal internal ring, the transversalis fascia must be sutured from the lower boundary of the ring upward to the cord, in this way elevating and diminishing the internal ring, with consequently a longer and more oblique canal. The various steps in the anatomical repair of oblique inguinal herna consisted of (1) the removal of the sac, with redundant parietal peritoneum. (2) Repair of the internal ring. (3) Protection of the ring by suture of the internal oblique muscle to Poupart's ligament. (4) Reunion of the aponeurosis of the external oblique muscle with the formation of a proper external ring.

Accidents and Complications in Goiter Operations.—Dr. CHARLES H. MAYO of Rochester, Minn., said accidents and complications were the cause of most of the deaths following operations upon goiter. Hemorrhage was a serious accident. When secondary, it was usually from muscle inclusion in ligating the inferior thyroid artery. Preservation of the posterior gland capsule tended to preserve the recurrent laryngeal nerves. also the parathyroid bodies. The greatest danger of parathyroid injury was in secondary operations for goiter.

Diagnosis and Treatment of Renal Calculi.—Dr. DANIEL N. EISENDRATH of Chicago discussed the influence of the presence of renal calculi upon the kidney in which they were lodged, as well as upon the opposite one. The number of cases in which calculi were found in both kidneys simultaneously was increasing. The chief points in the diagnosis so far as symptoms were concerned were hematuria, pain, and the passage of calculi. The treatment was considered chiefly from a surgical standpoint. The operation of choice was nephrotomy and pyelotomy. The relative merits and disadvantages of each were pointed out.

The Removal of the Gall-bladder.—Drs. ARCHIBALD MACLAREN and H. P. RITCHIE of St. Paul, in a joint paper on this subject, said that cholecystectomy was performed 21 times in 165 operations upon the gall-bladder, liver, and pancreas. The reasons for removal of the gall-bladder were: Contracted and useless gall-bladders in 10 cases; dilated and hypertrophied in 6 cases: phlegmonous and gangrenous gall-bladders, 1 case; empyema, 2 cases; mucous fistula, 2 cases. Three deaths had occurred—14.2 per cent. mortality. The gall-bladder was removed in three cases in which the common duct was involved. It would have been impossible to have used them in any subsequent operation. They believed in leaving the gall-bladder in common-duct cases for the purpose of cholecystenterostomy if it could be so used when needed. Both drainage and ligation of the cystic duct were proper procedures and depended upon the individual case. Nine cases were reported in which contracted and cystic gall-bladder empyema from typhoid fever and other conditions had been left and the patients had remained well from varying periods up to nine years. Many times after drainage, bile would not commence to flow until the fourth or even up to the seventh day. There were many cases in which the gall-bladder was so definitely diseased that there would be no question as to the necessity of removal, and anyone, no matter how limited his experience, would know that such gall-bladders ought to be removed. Those in which it was difficult to decide were the cystic gall-bladders, where the stone had been impacted a short time, or those which presented small hemorrhagic spots, or moderate-sized perforations. And they believed with Deaver that in case of doubt drainage should be used. Pancreatic disease occurred frequently in gall-bladder diseases, and drainage was necessary for cure.

New Incision to Reach the Bile Tracts.—Dr. CLIFFORD U. COLLINS of Peoria, Ill., described a new incision through which to reach the bile tracts. It began at the inner edge of the sheath. The rectus muscle was separated from its sheath and retracted outward. The same diagonal incision was then made through the posterior wall of the sheath and peritoneum. A short transverse incision from the upper end, through the linea alba, and another from the lower end through the linea semi-lunaris completed it. The advantages were: (1) There was not a continuous opening down through the layers of the abdominal wall. The openings through the aponeurotic structures were protected by the uninjured muscle, which lay between them. (2) The intercostal nerves were not injured as they entered the muscle through its outer border. (3) It made a stronger closure where drainage was required. The tube or gauze held the rectus muscle to the outer side. When it was removed, the muscle slid over to its former bed and placed a barrier of uninjured muscle across the drainage tract. (4) No injury was done to the muscular structure.

He also presented an instrument to facilitate the removal of stones from the first portion of the common duct. It consisted of forceps with an incomplete ring at the end of each jaw covered with rubber tubing. If the stone was found in the first portion of the common duct, or could be pushed up into the first portion, the lower jaw of the forceps was passed into the foramen of Winslow below the stone. When the jaws were closed, the incomplete rings would surround the stone and it might be drawn up into the incision.

Pericolitis.—Dr. JABEZ N. JACKSON of Kansas City, Mo., said that the term pericolitis had been generally vaguely used to describe adhesions about the colon, and at most times of an unknown origin. He believed that there was a form of pericolitis which had a distinct pathological identity, and was characterized by a distinct clinical picture. This pericolitis was characterized by the formation of an apparently entirely new layer of distinctly vascularized peritoneum in which the vessels were parallel and appeared to begin on the outer side at the root of the mesocolon, whence they advanced on to the colon, and then generally passed in the direction parallel to the long axis of the ascending colon. This membrane served to bind the ascending colon close to the posterior abdominal wall, and the longitudinal strands tended to produce a shortening and often a marked angulation of the colon. Sometimes this membrane passed across the ascending colon and up onto the transverse colon, which was then drawn downward and to the right until the transverse colon paralleled the ascending colon and distinct angulation was produced at the hepatic flexure above and below where the transverse colon turned back. With this latter condition the stomach was always drawn down and a mechanical gastroptosis was produced. The general effect of this membrane was a mechanical interference with the free peristalsis of the colon, also the stomach, thus producing stagnation, distension, pain, flatulency, and a train of nervous symptoms distinctly neurasthenic in character. This condition was believed to be of very frequent occurrence, and must have been observed by all surgeons of experience, but thus far had not been adequately described. He had found that this membrane could be dissected off *in toto*, and when this was done the mobility of the colon was restored.

Gastric and Duodenal Ulcer.—Dr. W. D. HAINES of Cincinnati presented the autopsy findings in a large series of examinations, with special reference to ulcer cicatrices. A strong plea was made for the removal of the gland-bearing tissue between the lesser curvature of the stomach and the pancreaticosplenic group of glands in operating for cancer of the pylorus. A concise résumé of the diagnostic features of gastric and duodenal ulcer, together with their differential diagnosis, was followed by a discussion of the surgical treatment of chronic ulcer. By pushing an instrument through the crater of the ulcer-producing artificial perforation, ligating the surrounding varicose vessels and turning in the margin of the ulcer by two layers of serous

sutures, local rest was obtained for the inflamed indurated tissues, and a gastrojejunostomy completed the technique. It was shown that nearly all gastric cancers had their origin in chronic ulcer.

Mistakes in Diagnosis in the Upper Abdomen.—Dr. James E. Moore of Minneapolis made no effort to elucidate obscure or moot-points in diagnosis, but endeavored to point out some common errors that could and should be avoided. The principal reason for mistakes in diagnosis in all regions of the body was lack of careful and systematic examination, and the two special reasons for mistakes in the upper abdomen were difficulty in palpitation and the comparatively recent origin of upper abdominal surgery. He cited a case in which two operations had been done, one for appendicitis and one for gallstones, and in which the whole trouble was due to splanchnoptosis. He pointed out the dangers of a false history given by the patient, particularly when she was neurasthenic. Every patient, especially every female patient, coming for examination of conditions in the upper abdomen accompanied by abdominal crises, should be carefully examined with a view of establishing the presence or absence of splanchnoptosis. It was not safe to conclude in the presence of splanchnoptosis that the patient was not suffering from other pathological conditions, because they were oftentimes combined. The evidences of ptosis of the various organs were so plain that they should always be discovered when proper examination was made. The liver was more frequently misplaced and misshapen than was generally understood, and was very liable to give rise to mistaken diagnoses. He warned the profession against the dangers of overlooking pathological conditions amenable to surgical treatment in neurasthenic patients. Pott's disease in its early stages, when located in the middle or upper dorsal region, caused pain that had frequently been the cause of mistaken diagnoses. This mistake could usually be avoided by ascertaining the presence or absence of rigidity of the spine.

Peritoneal Adhesions.—Dr. A. W. Abbott of Minneapolis said the cause of peritoneal adhesions was often obscure. Rough handling, hemorrhage, and traumatism were given more credit than they should receive. The relation between adhesions and symptoms was very contradictory. Extensive adhesions often were not accompanied by symptoms, and *vice versa*, severe symptoms were accompanied with very few adhesions.

The Versatile Omentum.—Dr. Frederick A. Dunsmoor of Minneapolis referred to the importance of the functions of the omentum in surgical practice. It was his practice to use the omentum as a patch for wounded intestine or denuded peritoneum, or to fill in ulcerations which were not otherwise readily closed. When large pus cavities were opened, after removing pus and wiping contaminated parts with iodoform gauze, the omentum was in all cases, where possible, made to adhere to the infected part instead of using a drainage tube. The author reported two cases illustrating how this most important organ might be utilized. His conclusions were: 1. It seemed sensible to follow natural and physiological efforts in attempts at cure. 2. The functions of the omentum to combat infection and drain dangerous elements from the peritoneal cavity were well established. 3. We should aim to secure the assistance of such functions, and at the same time use ingenuity to prevent permanent adhesions, which might be harmful. 4. We should deprecate the wasteful amputation of parts of the omentum appearing redundant or occupying the hernial sac. 5. That damaged, over-affected or strangulated portions of the omentum should be removed, in order that greater utility might be possible from the portion remaining.

Colles' Fracture.—Dr. J. W. Andrews of Mankato, Minn., discussed the surgical anatomy and the reasons for the characteristic deformity in Colles' fracture. He spoke of making the diagnosis by inspection. Crepitus and increased mobility were rarely present. An anesthetic was necessary for complete reduction, if not for accurate diagnosis. The injuries sustained by the soft tissues were extensive and important. In this form of fracture rapid bony union was the invariable rule. The prevention of deformity was not always possible.

The Cancer Question, with Special Reference to the Treatment of Cancer of the Breast.—Dr. J. E. Summers of Omaha, Neb., said the subject of cancer deserved equally as much attention by the laity as did that of tuberculosis. More women died of cancer than of tuberculosis. In a better education of the public lay the hope of the prevention of cancer. In its early recognition lay the promise of cure. He narrated some personal observations on cancer of the breast.

The following papers were read: "Splenic Anemia," by Dr. Van Buren Knott of Sioux City, Iowa; "The Surgeon and His Ideals," by Dr. W. E. Rochford of Minneapolis; "Diagnosis and Treatment of Cancer of the Uterus," by Dr. George C. Barton of Minneapolis; "Abdominal Pregnancy; Report of a Case, with Operation and Delivery of the Living Child," by Dr. J. N. Warren of Sioux City, Iowa; "Treatment of Retrodisplacements of the Uterus," by Dr. C. A. Stewart of Duluth, Minn.

Officers.—*President,* Dr. A. L. Wright of Carroll, Iowa; *First Vice-President,* Dr. J. F. Percy of Galesburg, Ill.; *Second Vice-President,* Dr. W. B. Haines of Cincinnati, Ohio; *Secretary-Treasurer,* Dr. Arthur T. Mann of Minneapolis, Minn.

Place of meeting, Omaha, Neb.; time, December 20 and 21, 1909.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held December 21, 1908.

The President, Dr. Robert T. Morris, in the Chair.

Gastric Neuroses.—Dr. John B. Deaver of Philadelphia read this paper. He said there was perhaps no single word in medical terminology that had been made to cover so many deficiencies in learning and diagnostic acumen as the term "neurosis," and he referred to the complexity of the classification and description of gastric neuroses in the text-books, the diversity of opinion concerning their causation, and the innumerable modes of treatment suggested by various authors. There could be no doubt, however, that there were certain morbid gastric conditions which had been and were still classified as neuroses, and that the surgeon as well as the medical practitioner was often called upon to confirm a diagnosis or suggest a treatment. As a fundamental principle, we could safely state that a gastric neurosis without other neuroses or neurasthenic conditions was a most rare thing, although the gastric symptoms might so overshadow all others that attention was directed only to them. Of the sensory disturbances, we found more or less anorexia or at least capriciousness of appetite in almost every case. True gastralgia he had found very rare. Of the secretory disturbances, hyperchlorhydria was by far the most important. It was far more frequent than hypersecretion or gastrosuccorrhea, which in its true form was indeed very rare, or than deficiency in hydrochloric acid in the gastric juice. Vomiting, eructations, and colic were as a rule but symptomatic. We might have often repeated attacks of vomiting, or vomiting of special articles of diet, in which operation or autopsy failed entirely to give even a clue to the causation. Atony of the stomach could not at times be considered as anything but a neurosis, and its treatment fell fully as much within the province of the surgeon as

of the internist. Finally, we had that vague group of symptoms, sensory, motor, and secretory combined, which in the absence of any definite or tangible demarcation had been called "nervous dyspepsia." A gastric neurosis was a thing of infinite variations, and the diagnosis was most difficult. The most important feature in the diagnosis was the eliciting of a careful history, which would show us the general neurasthenic condition of the patient. His ocular or cardiac symptoms might give us a clue. Carcinoma in its early stages was more often considered a gastric catarrh or nervous dyspepsia than it was recognized. The same was true of gastric ulcer. The speaker also referred to gastric neuroses of various forms associated with some lesion outside of the stomach, such as the gall-bladder, appendix, the kidneys, or pelvic organs. He said it was evident that text-books dealing with diseases of the abdominal organs must be rewritten, as the descriptions they now contained of diseases of those organs were of no moment at all in making an early diagnosis. Until they were rewritten on the lines of living pathology, they would be useless in the early recognition of these diseases. We were coming to recognize more clearly every year the fact that the various organs concerned in digestion formed a system correlated in every part. The stomach, intestines, biliary system, and even the appendix, the latter often described as functionless, did their work regularly in orderly sequence to accomplish the preparation of food for assimilation. In discussing the attitude of the surgeon toward cases of gastric neuroses, Dr. Deaver said it should be "hands off," with but very few exceptions. These cases belonged to the internist and neurologist, and they were in need of rest, with general and special dietetic treatment. Removal of the primary mental cause was essential, and these patients demanded the most careful management if their recovery was to be assured.

Indications for Surgery in Gastric Disease.—Dr. Anthony Bassler first took up the subject of malignant disease of the stomach. He said the first factor in this connection was early diagnosis, and although gastric cancer was a digestive disorder of a primary nature and was frequently encountered, the recognition of the condition in its early stages was not always easy, and often an impossible matter in the medical way. The disease was met with so differently in its course, sometimes rapid, sometimes chronic, and always insidious in its beginning. Usually, it developed at the end of a prolonged dyspeptic condition, in which a history of an early gastric ulcer could often be obtained. There were no definite subjective symptoms in early cases that were characteristic. There might be increasing anorexia, occasional nausea and vomiting, distress after meals, a sense of oppression, distaste for meats, and so on, and, again, not one local symptom downfall of from one to four per cent. of hydrochloric dilatation, and tumor were all late local symptoms. It might be said that the diagnosis of early cancer of the stomach could practically never be made by physical diagnostic means alone. Upon what, then, must we depend? In all middle-aged persons who came under observation for digestive disturbance, the first diagnosis was between cancer and the benign affections, and in the persistency of a continued clinical course—whatever the diagnosis or the treatment—cancer should be suspected, and the case became surgical after the following findings had been obtained: The securing of a piece of carcinoma tissue; a short upward curve, followed by a steady downfall of from one to four per cent. of hydrochloric acid a week, with a corresponding increase in the quantities of the organic acids; when test meals, carefully removed, usually contained blood in small quantities; when an increased bacterial flora of streptococci, staphylococci, diplococci, or streptobacilli were present in test meals, and the same type of organism was always found in large numbers and apparently did not originate from the saliva or sputum; when pus cells were always present in the empty stomach, and sarcinæ were not found in the test meals; when slight evidences of gastric retardation and fermentation existed or took place; and, finally, when the patient, weighed stripped each morning before breakfast, and after the contents of the bladder and rectum had been voided, showed a steady loss of weight. Assuming that after close attention to a suspicious case, the foregoing findings had been obtained, an exploratory incision should be advised immediately. Dr. Bassler next discussed gastric ulcers, which, when acute and under ordinary conditions, were medical affections. When they did not heal completely or perforated, bled too freely, or developed sequelæ, such as marked cicatricial contractions, pyloric stenosis, perigastric adhesions, or degenerated into carcinoma, they became surgical affections. The last class of cases in which operations were indicated were those with the presence of benign growths, such as large-size obstructing polypi or papillomata. The congenital stenoses were also included, as well as those cases of foreign substances in the stomach, as hair balls, or the swallowing of improper articles, as might be observed in those of vicious habits, such as the hysterical or the insane. Finally, the speaker emphasized the fact that the internist must be fair to his patient, and deliver to the surgeon many of the cases of generally termed "chronic dyspepties" when these did not improve or became worse under his care, and in which surgery offered possibilities of a better therapy than would be at his command.

Dr. George E. Brewer said he had been especially interested in that part of Dr. Deaver's paper that related to gastric neuroses, because of the not infrequent mistakes that were made by the surgeon in dealing with those conditions. While the general practitioner and the internist, as a rule, were prone to wait too long before advising operation in organic lesions of the stomach, the surgeon, on the other hand, spurred on by the brilliant work done during the past five or six years in relieving chronic gastric lesions, was inclined to operate more freely than he perhaps would after longer experience. About two years ago, Dr. Brewer said, he collected eighteen cases of operation done by him on the stomach during one year, and in five of these absolutely no benefit followed the operation. In every one of these five cases he was so firmly convinced by the symptoms that he was dealing with an organic lesion, although there were no evidences of it, that he did a gastroenterostomy. Subsequently, he became convinced that they were examples of gastric neuroses. This was well shown in the following case: The patient was a young woman who had vomited incessantly for six weeks, who was referred to him from the medical side of the hospital for immediate operation. The gastric analyses were of little assistance, the only symptoms being the persistent vomiting and tenderness. An exploration of the stomach showed nothing abnormal. In spite of this, a gastroenterostomy was done. The operation made the patient infinitely worse. The vomiting persisted, and she became weak and exhausted. Finally, she developed symptoms of a general neurasthenia, with peculiar sensations in various regions of the body, and with the advent of these symptoms, her vomiting ceased. In another of the five cases that were not helped by operation the patient was a most intelligent person, who gave a very distinct history, which was attributed to an organic lesion of the stomach. The operation revealed nothing, and the patient's symptoms were aggravated by it. She developed a general traumatic neurasthenia, which persisted for a year. In operating on cases of this character, Dr. Brewer said, he thought a safe rule to follow was not to do a gastroenterostomy in patients where no

lesion was discoverable by a thorough exploration. The speaker referred to the great progress that had been made during the past decade or two in the diagnosis and surgical treatment of gastric cancer, a condition which was formerly looked upon as absolutely hopeless. Now, we were saving a certain number of these cases, and Professor Hartmann of Paris recently told him that he regarded his results in cancer of the stomach as equal to those of cancer of the breast. It was to be hoped that with still more refined methods of diagnosis, especially those relating to gastric analyses, the results would be still better, but even now they were surprisingly good, when we considered the fact that we were dealing with an organ that was hidden from view, and not with cancer of the external surface of the body. Personally, he was firmly convinced that the greatest advance that could be made in reducing the death rate from cancer of the stomach was to advocate early exploratory operation. If the facts were clearly explained to these patients, he believed that most of them would be willing to submit to an operation in which there was comparatively little risk rather than take the even remote chance of suffering from a disease which, if allowed to take its course, would result fatally within two years.

Dr. Max Einhorn said that, while the diagnosis of certain gastric conditions was difficult, there were some that we could recognize with a fair degree of certainty. He was glad to hear that both Dr. Deaver and Dr. Brewer were opposed to operating in neurosis of the stomach, even of a severe type. Personally, he did not believe in advocating an operation simply because the patient was not doing well under non-operative treatment; we should have a certain aim in view or hope to accomplish something if the operation was successful. To operate simply for the suggestive effect of the operation was unworthy of both physician and surgeon. Dr. Einhorn said he saw many cases of gastroptosis that did not require operation at all, and were cured by bandaging and building up the general nutrition. He thought that at least 95 per cent. of these cases were amenable to this method of treatment. He did not believe that gastroptosis ever gave rise to stagnation of food, and the condition we had to deal with was entirely distinct from that occurring in real dilatation of the stomach, with obstruction of the pylorus, which had to be relieved by surgical means. After two or three weeks' observation we could decide the degree of pyloric obstruction, and whether an operation was necessary or not. In many cases where the obstruction was not of a high degree the patients could get along in comparative comfort and enjoy a moderately free diet. So long as gastroenterostomy was still attended by a certain mortality, he did not feel justified in recommending early operation as a routine measure in all these cases. For the same reason, he was not in favor of indiscriminate exploratory operation in all cases of gastric disease where there was a possibility—say one in ten—that it might be cancer. On the contrary, he was in favor of delay and further observation in such cases. Such conditions were so frequent that if we operated in every instance with the idea that the case might be one of cancer, it would entail an endless number of needless operations, and, furthermore, the same patients might require repeated operations. His own plan in these cases was as follows: When the diagnosis of cancer of any part of the digestive tract was made, operate as soon as possible. When, after a thorough examination, the probabilities were evenly divided in favor of malignant disease, operate. In closing, Dr. Einhorn said that a cancer of the stomach was not always recognized, even upon exploratory operation, and he emphasized the thought that, instead of trying to draw a hard-and-fast line between medical and surgical cases, the internist and the surgeon should unite, with a single object in view, and that to help the patient.

Dr. Robert Coleman Kemp said that in cases of hyperchlorhydria, to differentiate between this condition and possible gastric ulcer, to the importance of which Dr. Deaver had referred in his paper, certain checks might be used, namely, frequent analyses of the gastric contents, and especially the examination of the gastric contents and of the stools for the presence of occult blood. In hyperchlorhydria we might also expect to accomplish something by intelligent medicinal and dietetic treatment, so that careful observation of the subsequent clinical course of these cases was of diagnostic value. The symptoms of hyperchlorhydria might simulate gall-bladder disease, and it was not always easy to differentiate between these two conditions. Indeed, they might occur together. The treatment of both, fortunately, was very similar. An examination of the stools and the detection of gallstones might clear up the diagnosis. Dr. Kemp said he had seen several cases of impaction of the caput coli that simulated appendicitis. In the early recognition of cancer of the stomach the data furnished by gastric analyses were of very little value. The comparative frequency with which cancer was engrafted upon an old gastric ulcer should be borne in mind. The speaker said he agreed with Dr. Brewer that an early exploratory operation should be urged in every case of gastric disease in which there was even a remote possibility of cancer—even when the chance of its being cancer was one to twenty, and that the present mortality was due to neglect of early exploration. By the time the typical gastric analysis was found and the tumor was palpable, the case had usually progressed beyond the stage of possibility of curative operation. Dr. Kemp said the symptoms of stenotic dilatation and atonic dilatation, to which Dr. Deaver had referred, were entirely different. With the latter, which he had found very common in his examination of insane patients, there was usually no vomiting, no peristaltic unrest, and the symptoms were chiefly those of intestinal toxemia. With stenotic dilatation, on the other hand, we had peristaltic unrest and vomiting, and relief in those cases could only be sought through an operation. In gastroptosis the speaker did not favor operation, as the condition usually only represented one phase of a general enteroptosis; it was part and parcel of a general abdominal relaxation which could be best treated by improving nutrition, and by the use of an abdominal support, preferably Rose's belt; or, in extreme cases, by Dr. Morris' operation of tightening up the abdominal muscles.

Dr. Ransford E. Van Gieson said we might properly look upon the stomach as the storm center for all sorts of reflex conditions and neuroses. He recalled a case of persistent vomiting in a young woman which was regarded as a pure neurosis and was relieved by various methods of treatment, especially when they were discussed in her presence. The girl finally died of inanition after two years of treatment. Cases of acute perforative ulcer of the stomach, Dr. Van Gieson said, were rare, and unfortunately were not preceded by symptoms which would call our attention directly to the stomach. In many instances there was no history of preceding pain, and the perforation might occur within a comparatively few hours. The speaker said that his experience was unlike that of Dr. Deaver in regard to continuous gastric symptoms being caused by gallstones. In many of the cases he had seen the patients were absolutely free from symptoms in the intervals between the gallstone attacks; as soon as the acute attack was over, digestion was apparently perfect, and there were no gastric symptoms whatever. He agreed with Dr. Kemp that gastroptosis was merely a single manifestation of a general abdominal relaxation, and that adhesive strapping by the Rose method was preferable to surgical intervention.

The President, Dr. Morris, said he had found that in a

certain number of cases perfect relief of the gastric symptoms followed correction of urinal defects. Many good ophthalmologists were not competent, however, in this particular field. The test might perhaps rest upon their ability to cure Ménière's disease and migraine. If any were known to do this regularly, then they might take up gastric neuroses. In speaking of gastric lesions of doubtful character, Dr. Morris said that here, as in other regions of the body, the diagnostic value of an immediate examination of frozen sections should not be lost sight of.

Dr. DEAVER, in closing, said that in dealing with a gastric neurosis it was his practice to have the patient gone over by a neurologist and to have not only a preliminary examination of the eyes, but also of the throat, ears and nose. He could recall a number of cases where the stomach symptoms cleared up after errors of refraction were corrected. He agreed with the various speakers that ptosis, *per se*, was not within the province of the surgeon. He did not approve of Dr. Einhorn's teaching of delay and further observation in cases where there was a possibility of cancer of the stomach.

Dr. A. ERNEST GALLANT emphasized the importance of early, careful and repeated examinations in cases of suspected gastric cancer. The speaker said that during his connection with the New York Cancer Hospital, fifty per cent. of all the cases brought there were inoperable.

Dr. FRANZ TOREK said he could not subscribe unreservedly to the statement made by Dr. Bassler that when a cancer of the stomach was of such a size that it was palpable, the condition was practically always inoperable and fatal. The speaker said he could recall one case where the gastric tumor was not only palpable, but actually visible through the emaciated abdominal wall. In that case a resection was done four or five years ago, and the patient was still alive and showed no evidence of a recurrence.

Dr. BASSLER, in closing, said he did not believe that the diagnosis of early cancer of the stomach could be made by ordinary surgical means only, but that medically it could be made only by laboratory methods. In the making of such a diagnosis one could not depend upon gastric symptoms. In most instances cancer of the stomach began insidiously, with perhaps only slight anorexia, and some increase in the fermentation of foods in the organ. The patients were usually over 40 years of age, and a number gave a history of previous ulcer or diseased condition of the stomach. An exploratory operation could usually be done under cocaine anesthesia. Patients would consent to the cocaine method, but would balk until too late at ether. The main reason of this was that those afflicted with the early disease did not consider themselves ill enough for operation in the broad sense.

College of Physicians of Philadelphia.

At a stated meeting, held January 6, Dr. JOHN H. GIBBON read "A Memoir of the Late Dr. John H. Packard." Dr. GEORGE E. PFAHLER presented a communication entitled "The Roentgen Rays as an Aid in the Diagnosis of Carcinoma of the Stomach," with lantern demonstration. He pointed out the necessity of depending upon the *x*-rays merely as an adjunct in the diagnosis, to be taken into consideration in connection with the history, symptoms, and other physical signs. The use of the fluoroscope will yield the best results, but it is attended with danger, and several valuable lives have been sacrificed on the altar of this method of examination. By means of improved methods exposures may be brief, and satisfactory radiographic plates can be obtained. By the employment of bismuth emulsions the size, shape, and position of the stomach can be determined, as well as the condition of the walls of the viscus. An election for officers was held, with the following result: *President*, Dr. James Tyson; *Vice-President*, Dr. G. E. de Schweinitz; *Secretary*, Dr. Thomas R. Neilson; *Treasurer*, Dr. Richard H. Harte.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS, NEVADA.

November, 1908.

ANATOMY.

1. Describe the circle of Willis.
2. Give the origin, insertion, and function of the flexor longus hallucis.
3. Bound the scaphoid or navicular tarsal bone.
4-5. Give location and approximate number of submaxillary lymphatic glands.
6-7. Give length and weight of medulla oblongata. About what proportion does it form of the whole cerebrospinal axis?
8-10. What part of the body weight does the liver form in the adult male? In the female? In the fetus at the fourth month?

PHYSIOLOGY.

1. What is the function of the sixth (abducens) nerve?
2. Describe a complete physiological revolution of the heart.
3. Name the secretions of the alimentary canal and give the functions of each.
4. Describe the process of segmentation of the ovum.
5. What are amyloid foods, proteid foods? Give example of each.
6. Describe the action of the kidneys. Give the normal constituents of urine.
7. What test should be applied to sustain the integrity of (*a*) the superficial reflexes, (*b*) the deep reflexes?
8. What are the accepted theories as to the origin of (*a*) the red blood corpuscles, (*b*) the white corpuscles?
9. State the functions of the fifth cranial nerve.
10. Describe the portal circulation; renal circulation.

CHEMISTRY AND TOXICOLOGY.

1. What class of food should be excluded from the diet when iodic preparations are being used?
2. Why should pepsin and pancreatin not be given in combination?
3. When opium and acetate of lead are combined, what reaction takes place?
4. Give another example of a common prescription in which a chemical change takes place.
5. Describe a method for determining the quantity of sugar in urine.
6. Describe various methods by which poisons kill.
7. How would you prepare the antidote for arsenic?
8. What is the first indication of excessive use of carbolic acid externally?
9. Describe a case of lead poisoning.
10. Give antidotes for silver nitrate, belladonna, strychnine, tartar emetic.

MATERIA MEDICA AND THERAPEUTICS.

1. Name four preparations of opium; give the morphine strength of each.
2. Give classification of cathartics with example of each.
3. What action would you expect from five minim, one dram, and one ounce doses of turpentine?
4. Indicate the various uses of iron.
5. Name five remedies having a special action on the heart. Indicate field of usefulness for each.
6. What is eliminative treatment? Name five drugs of special use in this line.
7. Indicate the therapeutic uses of quinine.
8. Name five coal-tar derivatives; give indications for and against their use.
9. Indicate the uses of salicylic acid, its antagonists, and incompatibles.
10. Give the various routes by which medicines are introduced into the organism.

BACTERIOLOGY.

1. What methods would you use to prevent the spread of tuberculosis when the patient was unable to go to a sanatorium?
2. How would you manage a case of typhoid fever to prevent its spread?
3. What is immunity?
4. How would you determine the presence of the malarial parasite?
5. Describe the *Staphylococcus pyogenes aureus*. Where is it found?

6. Define ptomains, toxins, flagella?
7. Discuss the modes of infection by the tubercle bacillus.
8. Describe the cholera bacillus.

PATHOLOGY.

1. Give the pathology of diphtheria.
2. Describe microscopically the lesions found in the bowel in a case of typhoid fever.
3. Give the pathology of hypostatic congestion of the lungs.
4. Give the pathology of chronic interstitial nephritis.
5. Give the pathology of pericarditis.
6. Describe in full the pathology of gout.
7. Give the pathology of cerebral hemorrhage.
8. Give the pathology of chronic myelitis.

PRACTICE OF MEDICINE.

1. Give etiology, symptoms, and treatment of cholera infantum.
2. Describe the symptoms of any one disease of the pancreas.
3. Give the diagnosis and treatment of tetanus.
4. Define neurasthenia and give etiology, symptomatology, and treatment.
5. Write a short article on Addison's disease.
6. Give causes, symptoms, and treatment of simple catarrhal jaundice.
7. Differentiate epilepsy and hysteria.
8. What is the treatment for pertussis?
9. What are the manifestations in a case of hereditary syphilis?
10. Give the symptoms and the treatment of general paresis.

OBSTETRICS.

1. During the fifth month of pregnancy how does the liquor amnii compare, in weight, with the weight of the fetus?
2. May syphilis be transmitted by the father to the embryo without infecting the mother?
3-4. Give treatment of chorea gravidarum in pregnancy. What is the percentage of mortality in such cases?
5. About what is the average duration of labor in multiparæ? In primiparæ?
6-7. Should the membranes be punctured in the case of a primipara at the beginning of the second stage of labor? Give reasons for or against such procedure.
8. Give symptoms, causes, and treatment of uterine inertia.
9. What three signs indicate that labor has actually begun?
10. Give treatment for presentation of the greater fontanel.

SURGERY.

1. Describe the ligation of the femoral artery at apex of Scarpa's triangle.
2. How would you reduce a dislocation of the inferior maxillary bone?
3. Define volvulus and give its treatment.
4. Relate the difference between a sinus and a fistula.
5. How is resection of the elbow joint performed?
6. Name the causes of intestinal obstruction.
7. What structures are divided in the operation for strangulated hernia?
8. Describe the operation for ligature of the subclavian artery at its second part.
9. Give symptoms and treatment of nevus.
10. What are the symptoms of morbus coxæ in its different stages?

GENITOURINARY AND DERMATOLOGY.

1. Enumerate causes of cystitis, and how you would treat it.
2. What complications may arise in cases of acute urethritis?
3. Describe an operation for circumcision.
4. Describe syphilis in all its stages, and give treatment for each stage.
5. Differentially diagnose chancre, chancroid, and herpes progenitalis.
6. What is eczema?
7. What are the symptoms, cause, and treatment of scabies?
8. What are the causes, symptoms, and treatment of urticaria?
9. Describe alopecia areata.
10. What are the causes, symptoms, and treatment of prurigo?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS NEVADA

November, 1908.

ANATOMY.

3. The *scaphoid or navicular tarsal bone* is bounded: *in front*, by the three cuneiform bones; *behind*, by the astragalus; and *externally*, by the cuboid.

4 and 5. The *submaxillary lymph glands* are in the digastric triangle; they vary from eight to twelve in number.

6 and 7. The *medulla oblongata* is about one inch to an inch and a quarter in length; and its weight is about a quarter of an ounce. It forms about 1/125 of the whole cerebrospinal axis.

8 to 10. The *liver* forms about 1/40 part of the body weight of an adult male; about 1/36 in the adult female; and about 1/10 in the fetus at the fourth month.

PHYSIOLOGY.

1. The sixth (abducens) nerve is the motor nerve to the external rectus muscle of the eye.

2. A *complete physiological revolution of the heart* or *cardiac cycle* includes all the changes which occur between the commencement of one heart-beat and the commencement of the next; it consists of the alternate contractions (or systole) and relaxations (or diastole) of the auricles and ventricles of the heart. The contraction of the two auricles takes place simultaneously and is followed by the simultaneous contraction of the two ventricles; then follows a period during which the whole heart is in a state of diastole. The cycle then begins again with the auricular systole.

3. The secretions of the alimentary canal are: Saliva, gastric juice, pancreatic juice, bile, and succus entericus.

The functions of the saliva are: (1) To moisten the mouth, (2) to assist in the solution of the soluble portions of the food, and thus (3) to administer to the sense of taste, (4) to lubricate the bolus of food, and thus (5) to facilitate the acts of mastication and deglutition, and (6) to change starches into dextrin and sugar.

The functions of the gastric juice are: (1) To change proteids into proteoses and peptones, and (2) to curdle the casein of milk.

The functions of the pancreatic juice are: (1) To change proteids into proteoses and peptones, and afterwards decompose them into leucin and tyrosin; (2) to convert starch into maltose; (3) to emulsify and saponify fats; and (4) to cause milk to curdle.

The functions of the bile are: (1) To assist in the emulsification and saponification of fats; (2) to aid in the absorption of fats; (3) to stimulate the cells of the intestine to increased secretory activity, and so promote peristalsis, and at the same time tend to keep the feces moist; (4) to eliminate waste products of metabolism, such as lecithin and cholesterin; (5) it has a slight action in converting starch into sugar; (6) it neutralizes the acid chyme from the stomach and thus inhibits peptic digestion; (7) it has a very feeble antiseptic action.

The functions of the succus entericus are: The secretion of enterokinase, secretin, and erepsin, which assist the pancreatic juice in digestion.

5. *Amyloid foods* are foods containing amyloses or starches. They contain no nitrogen, but are made up of carbon, oxygen, and hydrogen; the hydrogen and oxygen are in the proper proportions to form water. *Example:* Potatoes.

Proteid foods are foods containing proteids. They contain nitrogen, and have a composition similar to that of albumin; other elements contained in them are carbon, hydrogen, oxygen, and sometimes sulphur. *Example:* Meat.

6. The mechanism of the *secretion of urine by the kidneys* is twofold: (1) By filtration, most, if not all, of the fluid is eliminated, and also inorganic salts; this depends upon blood pressure, and takes place in the glomeruli. (2) By cell activity and selection, in the cells of the convoluted tubules, the urea and principal solids are eliminated.

The normal constituents of the urine are: Water, urea, uric acid, urates, hippuric acid, kreatinin, xanthin, hypoxanthin; sulphates, chlorides, and phosphates of sodium and potassium; phosphates of magnesium and calcium; nitrogen, and carbon dioxide.

8. (*a*) The *red blood corpuscles* have their origin in the red marrow of bones.

(*b*) The *white corpuscles* are formed in the spleen, lymph glands, and lymphoid tissue.

9. THE FUNCTIONS OF THE FIFTH CRANIAL NERVE. *First, or ophthalmic branch* supplies sensation to conjunctiva, and skin of upper eyelid, cornea, skin of forehead and nose, lachrymal gland, and skin of nose. *Second, or superior maxillary branch,* supplies sensation to skin and conjunctiva of lower eyelid, nose, cheek, upper lip, upper teeth, and palate. *Third, or inferior maxillary branch,* supplies sensation to external auditory meatus, side of head, mucous membrane of mouth, anterior two-thirds of tongue, lower teeth, and skin of lower part of face. This branch, in addition, supplies motion to the muscles of mastication (Masseter, Temporal, External and Internal Pterygoids), and the Mylohyoid, and anterior belly of the Digastric.

CHEMISTRY AND TOXICOLOGY.

1. Starches.

2. Because *pancreatin* only acts in an alkaline medium; while *pepsin* only acts in an acid medium, and further becomes decomposed in an alkaline medium.

3. A precipitate results.

4. Potassium iodide and mercuric chloride.

5. Method for the *quantitative estimation of sugar in urine: Fehling's method:* The solution is made as follows:

I. Dissolve cupric sulphate..... 51.98 gm.
in water to.....500.00 c.c.

II. Dissolve Rochelle salt..... 259.9 gm.
in sodium hydroxide soln. sp. gr. 1.12 to 1,000 c.c. (Piffard).

When required for use, one volume of I. is to be mixed with two volumes of II. The copper contained in 10 c.c. of this mixture is precipitated completely, as cuprous oxide, by 0.05 gm. of glucose.

"To determine the quantity of sugar, place 10 c.c. of the mixed soln. in a flask of about 250 c.c. capacity, dilute with H_2O to about 30 c.c., and heat to boiling. On the other hand, the urine to be tested is diluted and thoroughly mixed with four volumes of H_2O if it be poor in sugar, or with nine volumes of H_2O if highly saccharine, and a burette filled with the mixture. When the Fehling soln. boils, add a few gtt. NH_4HO and then 5 c.c. of the urine from the burette, boil again, and continue the alternate addition of diluted urine and boiling of the mixture until the blue color is quite faint. Now add the diluted urine in quantities of 1 c.c. at a time, boiling after each addition until the blue color just disappears. Have ready a small filter, and, having filtered through it a few gtt. of the hot mixture, acidulate the filtrate with acetic acid, and add to it 1 gtt. soln. of potassium ferrocyanide. If a brownish tinge be produced, add another ½ c.c. of dil. urine to the flask, boil, and test with ferrocyanide as before. Continue this proceeding until no brown tinge is produced. The burette reading, taken at this point, gives the number of c.c. of dilute urine containing 0.05 gm. glucose, and this divided by 5 or 10, according as the urine was diluted with 4 or 9 volumes of H_2O, gives the number of c.c. of urine containing 0.05 gm. sugar. The number of c.c. of urine passed in twenty-four hours divided by 20 times the number of c.c. containing 0.05 gm. glucose, gives the elimination of glucose in twenty-four hours in grams.

Example: Urine in 24 hours =2.436 c.c.
Fehling's solution used = 10 c.c.
Urine diluted with 4 vols. H_2O
Burette reading = 18.5 c.c.

$\frac{18.5}{5} = 3.7 =$ c.c. urine containing 0.05 gm. glucose.

$\frac{2,436}{3.7 \times 20} = 32.92 =$ grams glucose eliminated in 24 hours."
(Witthaus' *Urinalysis.*)

6. *Poisons may kill,* by: Shock; by effect on heart, lungs and brain, and spinal cord; narcotism, asthenia, or tetanus; perhaps some chemical change in the blood.

7. The antidote for arsenic is a freshly prepared solution of ferric hydroxide; this may be prepared by keeping the two following solutions in separate bottles, and when needed it is only necessary to mix them and administer: (1) liq. ferri tersulphatis, ℥ij; aquæ, ℥vj. (2) magnesiæ, ℥iij; aquæ, ℥viij.

8. The *first indication of excessive use of carbolic acid externally,* is the dark color and smoky appearance of the urine.

9. The *symptoms of acute lead poisoning* are: "Metallic taste; dryness of the throat; thirst; severe colicky abdominal pains, referred particularly to the umbilical region, and relieved by pressure; pulse very feeble and slow; great prostration; constipation; urine scanty and red; violent cramps; paralysis of the lower extremities; convulsions, and tetanic spasms.

The antidotal treatment consists in administering "magnesium sulphate, which brings about the formation of the insoluble lead sulphate, while the purgative action of the magnesia is also useful. It should be preceded by an emetic, or by the use of the stomach tube."

10. The *antidote:* for *silver nitrate,* is solution of sodium chloride; for *belladonna,* is morphine, or tannin; for *strychnine,* is chloroform or chloral; for *tartar emetic,* is tannin.

MATERIA MEDICA AND THERAPEUTICS.

1. *Four preparations of opium:* (1) Powdered opium; (2) Deodorized opium; (3) granulated opium; (4) extract of opium. The first three contain from 12 to 12.5 per cent. of crystallized morphine; the last cpntains 20 per cent. of morphine.

2. *Cathartics are classified* as: (1) *Simple cathartics,* as Rhamnus purshiana; (2) *Laxatives,* as magnesia; (3) *Salines,* as potassium tartrate; (4) *Drastics,* as colocynth; (5) *Hydragogues,* as elaterium; (6) *Cholagogues,* as podophyllin.

3. From *turpentine,* given in *five minim doses,* I should expect a stimulant and expectorant effect; in *one dram doses,* an anthelumintic effect; and in *one ounce doses,* suppression of urine, strangury or death.

5. *Five remedies which have a special action on the heart:* Digitalis, aconite, strychnine, belladonna, and strophanthus.

6. *Eliminative treatment* is the method of treatment by the administration of agents which will cause the excretion or removal of noxious or waste matters from the system. *Five drugs useful in this line,* are: Castor oil, rhubarb, aloes, colocynth, elaterium.

8. *Five coal tar derivatives:* Carbolic acid, salicylic acid, salol, phenacetin, and resorcin.

10. *The various routes by which medicines are administered:* Mouth, stomach, rectum, respiratory tract (by inhalation), skin (by inunction, fumigation, hypodermically, by cataphoresis).

BACTERIOLOGY.

1. "The preventive measures which may be taken to reduce tuberculosis may be summarized as follows: (1) The compulsory notification of phthisis. (2) The removal of those conditions of domicile and of occupation which are known to promote the incidence of the disease, including the regulation of certain dusty trades. (3) The diffusion of knowledge (by medical men, leaflets, etc.) regarding the nature and modes of spread of the disease, and the precautions which should be taken in order to prevent its extension. (4) The testing of sputum and other suspected discharges, and of milk, meat, etc., supposed to be tuberculous—reports to be furnished free of charge. (5) Local authorities to undertake, without charge, the disinfection of houses recently occupied by phthisical persons. (6) The establishment of sanatoria and isolation accommodation for the cure of phthisical patients, and the isolation of those who are a distinct source of danger to fellow lodgers or workers. (7) the enforcement of measures against spitting in public conveyances and in places of public resort. (8) The efficient sanitary supervision of dairy farms, dairies, and milkshops. The periodical veterinary inspection and testing (by tuberculin) of milch cows, and the slaughter of tuberculous animals. The prohibition of the sale of milk of cows affected with tuberculosis. (9) The proper inspection of meat in public abattoirs, and the adoption of due precautions for the control of imported meat and milk." (Parkes' *Practical Hygiene.*)

2. To prevent the spread of typhoid fever: Flies should be kept out of the house as far as possible, by means of screens or otherwise; all discharges from the sick person must be disinfected; all utensils, dishes, etc., used by the patient must be thoroughly cleansed, and boiled every day; soiled linen must be soaked in a disinfectant solution before being washed; after each attendance on a patient, physicians, nurses, and others should wash their hands in a disinfectant; thorough sterilization of all bedding, etc., must be performed after the disease is over. Further, each household should boil all water that is to be used for drinking or for washing dishes, etc.; milk should be boiled also; and no ice should be put *in* water or other drink or food.

3. *Immunity* is the power of resistance of cells and tissues to the action of pathogenic bacteria. Immunity may be either natural or acquired.

Natural immunity is this power of resistance, natural and inherited, and peculiar to certain groups of animals, but common to every individual of these groups .

Acquired immunity is this resistance acquired: (1) by a previous attack of the disease, caused by the bacteria, or

(2) by the person being made artificially insusceptible. The conditions which give immunity from the pathogenic action of bacteria are: (1) a previous attack of the disease; (2) inoculation, with small quantities of bacteria, so as to produce a mild attack of the disease; (3) vaccination; (4) the introduction of antitoxins; (5) the introduction of the toxins of the bacteria.

4. *To determine the presence of malarial parasite:* A few hours before the chill, a drop of blood should be taken from the cleansed lobe of the ear or tip of the finger of the patient. The blood should be received on the center of a cover-glass, which should then be quickly placed, blood side down, on a slide. Search should be made with a one-twelfth oil immersion objective, and but little illumination. The ordinary tertian parasite appears as a small, pale, and ring-like body within the red corpuscles; it has an active vibratile motion; sometimes a dark pigment is present, and segmenting bodies or rosettes may be seen.

5. The *staphylococcus pyogenes aureus* is a small round cell which appears in clusters like a bunch of grapes; its diameter is about 0.8 to 1.0 mikron; it is facultative anerobic, has no flagella, is not motile, it stains readily with the anilin dyes, and is not decolorized by Gram's method; it forms an orange pigment on gelatin, potatoes and other media; it also liquefies gelatin.

It is *found* on the skin; in the nose, mouth, ears, and eyes, and under the nails; also in abscesses, boils, carbuncles, osteomyelitis, arthritis, empyema, and suppurative inflammations in general.

6. *Ptomains* are the putrefactive products of dead animal tissues, or fluids; they are basic, nitrogenous, and resemble alkaloids in their action.

Toxins are the products of pathogenic bacteria or ptomaines and leucomains, and are actively poisonous.

Flagella are delicate filaments which are attached to some bacteria, and are supposed to aid in their locomotion.

7. The *modes of infection of the tubercle bacillus,* are: The respiratory tract, by inhalation; the digestive tract (by food and drink); through the skin or mucous membranes, when abraded, or by inoculation.

8. The *cholera bacillus:* is a spirillum, actively motile, and with a flagellum at one end; it is curved, has rounded ends, and is about half the length of the tubercle bacillus; it stains readily with ordinary anilin stains, but not by Gram's method; it is easily cultivated on the usual media; it has but slight power of resistance; it liquefies gelatin, and does not produce pigment.

PRACTICE OF MEDICINE.

3. Tetanus. *Diagnosis:* Dysphagia; pain and stiffness in the muscles of the lower jaw and neck; tonic spasms of the muscles of the back, legs, and abdomen; the jaws become rigid and locked; opisthotonus and risus sardonicus are present. Tetanus may be confounded with poisoning by strychnine, but there are marked differences: In *tetanus,* the onset is gradual, is apt to begin with trismus, swallowing is difficult or impossible, the condition is persistent, consciousness is dulled or lost, and there is history of a wound or injury. In *strychnine poisoning,* the onset is more sudden, the muscles of the jaw and neck are generally the last to be affected, there are marked remissions with muscular relaxation, consciousness is retained, and there is no history of a wound or injury.

Treatment: Rest in bed in a dark, quiet room; tonics and nutritious food; opium, chloral, chloroform, or bromides to control the spasms; antitetanic serum has been used; the ideal method of treatment lies in prophylaxis by careful antisepsis in case of all wounds, particularly punctured wounds.

7.

Epilepsy.	Hysteria.
1. No apparent cause.	1. Cause, emotional.
2. Sudden and rapid onset.	2. Onset gradual, usually after some mental excitement.
3. Aura generally present.	3. Globus hystericus or palpitation.
4. Consciousness lost.	4. Consciousness generally preserved.
5. Pupils generally dilated.	5. Pupils normal.
6. Tongue often bitten.	6. Tongue never bitten.
7. Patient very liable to hurt himself.	7. Patient not liable to hurt himself; may injure others.
8. May be involuntary bladder and bowel discharges.	8. Never.
9. Of short duration.	9. Duration longer.

OBSTETRICS.

1. During the fifth month of pregnancy, the fetus weighs nearly 9 ounces; but the liquor amnii weighs a little more than this.

2. Yes; syphilis may be transmitted by the father to the embryo without infecting the mother.

3. and 4. *The treatment of chorea gravidarum in pregnancy:* Rest, both physical and mental; good hygienic surroundings; chloral, bromides, hyoscin, chloroform, arsenic, tonics, and sodium salicylate have all been recommended; induction of premature labor may be necessary. The *percentage of mortality* in such cases is about 30 to 35.

5. The *average duration of labor,* in *multiparæ,* is about ten or eleven hours; in *primiparæ,* is about fifteen hours.

6 and 7. No; there is no need to puncture the membranes at the *beginning* of the second stage. By puncturing, we would induce a dry labor and consequently prolong the labor and possibly turn the case from one of eutocia to dystocia.

9. *Three signs indicating that labor has actually begun,* are: (1) True pains; (2) dilatation of the os, with effacement of the cervical canal; (3) The "Show."

SURGERY.

4. A *sinus* is blind at one end and open at the other; while a *fistula* is open at both ends.

6. *The causes of intestinal obstruction* are: Strangulation through apertures, or by means of bands and contracting adhesions; impaction of foreign bodies or feces; the presence of tumors; volvulus or intussusception; intestinal paralysis; disease in the intestinal walls ultimately narrowing the lumen.

7. From without inwards, the coverings of hernia are as follows:

Direct Inguinal.	*Oblique Inguinal.*	*Femaral.*
Skin	Skin	Skin
Superficial fascia.	Supercial fascia	Superficial fascia
Intercolumnar fascia.	Intercolumnar fascia	Cribriform fascia
Conjoined tendon.	Cremasteric fascia	Crural sheath
Transversalis fascia	Infundibuliform fascia	Septum crurale
Subperitoneal tissue	Subperitoneal tissue	Subperitoneal tissue
Peritoneum	Peritoneum	Peritoneum

It is not always possible (or necessary) to distinguish all these layers.

10. Morbus coxæ. *Symptoms of first stages:* Night cries; lameness in the morning; a slight limp; tendency to become tired on slight exertion; wasting; spasm; pain; swelling; and deformity (either real or apparent).

Symptoms of Second Stage: Abduction, limping, pain, which is worse at night, apparent lengthening of the limb, abscess, atrophy of thigh muscles, flexion of thigh, effusion into hip joint, and there may be crepitation in the joint.

Symptoms of Third Stage: Flexion, adduction, and shortening of the limb, the joint may be dislocated or ankylosed, or suppuration may occur.

GENITOURINARY AND DERMATOLOGY.

1. Cystitis. *Causes:* Exposure to cold and wet; traumatism, calculus, use of cantharides and some other drugs; spread of urethral inflammation, pus, infectious diseases; vesical paralysis; enlarged prostate; bacteria.

Treatment: Remove the cause, if possible; rest in bed; the imbibition of plenty of milk and water, and the avoidance of all highly seasoned food; laxatives; diuretics; sitz bath; irrigation of the bladder with a hot, mild, antiseptic solution; hot fomentations to the epigastrium, and suppositories of opium, and belladonna are often helpful; sometimes intravesical medication is necessary.

2. *The complications of a urethritis* may be: Prostatitis, cystitis, pyelitis, epididymitis, inflammation of the vas deferens and of the seminal vesicles, periurethritis, retention of urine, bubo, inflammation of Cowper's glands, peritonitis, gonorrheal rheumatism, gonorrheal conjunctivitis.

4. *The first stage of syphilis,* is characterized by the *hard chancre.*

The second stage, by: Sore throat, mucous patches; the skin lesions or syphilides, which are characterized: By not itching; by being of a coppery or raw ham color; by being painless; by polymorphism, macules, papules, pustules, etc., being present at the same time; by being generally symmetrical. In this stage may also appear: Iritis, periostitis, and alopecia.

The third stage, is marked by: Anemia, gumma formation, periosteal nodes, headaches, endarteritis, and various other diseases.

5.

CHANCRE.	CHANCROID.	HERPES PROGENITALIS.
First lesion of a constitutional disease, viz., syphilis.	A local disease.	A local neurosis.
Due to syphilitic infection.	Due to contact with secretion from chancroid.	Due to irritation.
Generally a venereal infection.	Always a venereal infection.	May be non-venereal.
May occur anywhere on the body.	Nearly always on genitals.	Occurs generally on prepuce; may occur anywhere on genitals.
Period of incubation never so short as ten days.	Period of incubation always less than ten days (generally about three).	No incubation period.
Generally single.	Generally multiple.	Multiple vesicles occurring in crops.
Not autoinoculable.	Autoinoculable.	Not autoinoculable.
Secretion slight.	Secretion profuse and purulent.	Secretion little or none.
Slightly or not at all painful.	Generally painful.	Tingling and itching rather than painful.
As a rule only occurs once in any patient.	May reoccur in same patient.	Apt to reoccur.
Buboes are painless and seldom suppurate.	Buboes are painful, and usually suppurate.	Lymphatics seldom involved.

7. *Scabies* is a contagious, animal, parasitic disease, due to the *Sarcoptes scabiei*, characterized by burrows and a multiform eruption, and attended by severe itching. The eruption usually occupies certain areas where the skin is thin; these are the interdigital spaces, the flexor surface of the wrist and arm, the anterior and posterior axillary folds, the mammæ and nipples (in women), the umbilicus, the buttocks, the penis, the inner side of the thighs and legs, and the toes. The face is exempt except occasionally in infants. The itching is intense and worse at night. The affection is curable, but dermatitis may result from overtreatment.

Treatment consists in a thorough scrubbing with soap and warm water, followed by friction to dry the skin, and the application of sulphur ointment; the latter to be repeated morning and night for three days. The whole process may need to be repeated one or more times.

9. ALOPECIA AREATA. *Etiology:* The real cause is unknown; it has been regarded as a neurosis; as due to parasites; or as the result of malnutrition of the hair.

Symptoms: There are circumscribed round or oval patches of baldness, which may appear suddenly or gradually, generally in early adult life; the scalp appears unchanged or may be pale or hyperemic; there are no scales; occasionally the eyebrows or beard are involved.

It is distinguished from *Ringworm*, in that the latter is rare in adults, is characterized by scales in which are broken-off stumps of hairs with split ends, and a microscopical examination shows the presence of the tricophyton fungus in ringworm.

Texas.—Under certain conditions, this State now reciprocates with Ohio and Virginia. Ohio certificates issued since January 1, 1900, are accepted, and from Virginia since July 1, 1900.

Ohio.—The State Medical Board has received information that some medical students having preliminary educational requirements less than demanded by the Ohio law have been induced to attend medical colleges in other States, under the impression that after graduation they can return to and obtain a license to practise in Ohio under reciprocity. This should be corrected. All medical students who have or who contemplate matriculating in colleges in other States with such impression should understand that a license from another State is accepted in place of an examination only. The applicant in all other particulars must comply with the laws of Ohio and the rules of this board. The preliminary educational attainments must be the same as required of students of Ohio colleges.

PROSTATECTOMY.*

BY JOHN B. DEAVER, M.D., LL.D.,

PHILADELPHIA, PA.

PROSTATECTOMY, either partial or complete, is practically the only operation performed upon the prostate gland, except in acute suppurations. It would be hard to find another organ of the body whose functions and pathological conditions are so varied yet in which the endeavors of the surgeon cover a field apparently so limited.

Yet we should not be deceived by this seeming limitation in the operative field. While the immediate procedure has always the same object—removal of all or a part of the organ, the indications for surgical intervention are many, the methods of performing it numerous and the refinements of its technique vary almost with every individual operator of note.

The pathological processes of the prostate gland which may necessitate a prostatectomy can be divided into three classes:

1. Those in which enlargement or hypertrophy of the gland is the condition giving us the symptoms to be overcome.

2. Those in which the prostate is the seat of chronic disease causing local symptoms often associated with grave psychical conditions and in chronic gonorrheal prostatitis.

3. Those in which the prostate is the site of a malignant growth.

Simple hypertrophy of the prostate is the condition which most often demands the attention of the surgeon. When this condition exists it requires intervention, not because of any inherent danger or because of symptoms due to the prostatic condition *per se*, but because of the relation of the prostate to the bladder outlet.

The urethra passes through the prostate gland, which is composed chiefly of two lateral lobes—the true lobes of the prostate. At the neck of the bladder and in the floor of the prostatic urethra lies that mass of prostatic tissue which, when it becomes enlarged, gives rise to the erroneous idea of a median lobe. Granting, however, that there is no true middle lobe of the prostate, it may be convenient to term the enlargement of this portion an enlargement of the "middle lobe," and so it is often referred to by various authors, by some indeed in ignorance of its true pathological anatomy.

Hypertrophy of the prostate consists in an overgrowth of the adenomatous portion of the gland, with more or less accompanying increase in the fibrous connective tissue, and also at times with some increase in the muscular tissue. By some authors (Young) hypertrophy of the prostate is regarded as in most cases a true adenoma, while others (Watson) take a contrary view. However that may be, it will at once be seen that either the adenomatous or the fibrous proliferation may predominate. Should the adenomatous increase be the greater the prostatic tissue becomes greater in size but less in density, *i.e.* we have here the method of formation of the larger soft prostates met with. If the connective tisue overgrowth predominates, we have formed those hypertrophied prostates which are small, firm and densely adherent to the capsule.

Whatever be the process, there can be no doubt that any portion or any number of portions of the gland may become involved. Thus the lateral lobes may become larger without any marked median overgrowth, or the reverse may be true. In most instances, however, we have a coincident and fairly uniform enlargement of all of the prostatic tissues —in other words, a condition in which a partial prostatectomy would be a palliative and not a finally curative operation.

The distinction between carcinoma and ordinary hypertrophy of the prostate gland, while made with certainty by the microscopic examination of tissue removed, is clinically not such an easy one. That is to say, while the disease is still localized to the prostate itself, the clinical symptoms which demand prostatectomy are precisely those which occur in hypertrophy and to which I shall later refer in discussing the indications for the operation.

Chronic gonorrheal prostatitis has been the last important condition of the gland to be recognized. In former years it was practically never recognized, but later studies have shown that the prostate is often the cause of the persistence of gonococci in the genital tract in those cases of urethritis which are very refractory. Not alone this, but a chronic gonorrheal inflammation of the gland often gives rise to such profound neurasthenic and psychical phenomena that the local lesion becomes of secondary importance, while the whole life of the patient is overshadowed by the systemic results of a dormant lesion.

It is not my purpose here to enter upon the symptomatology of the various forms of prostatic disease except in so far as an understanding thereof is necessary in forming a summary of the indications for the operation of prostatectomy.

In simple hypertrophy the indication for prostatectomy is such an increase in any portion of the prostate that the normal voiding of urine is greatly interfered with. A prostate which enlarges but does not prove an obstruction to the outflow of the bladder contents is not *per se* dangerous, nor should it be in any way tampered with. We know that some grade of prostatic hypertrophy is, one might say, the rule in men over fifty-five years of age, yet in most of them there are never any evil effects

*Read by title at Meeting of Southern Surgical and Gynecological Association, St. Louis, December, 1908

therefrom. It may be thought by some that in an enlarged prostate the danger of malignant degeneration is such as to render prostatectomy advisable in many more instances than it is now performed, yet the comparative rarity of prostatic carcinoma and the frequency of prostatic hypertrophy do not lead me to take this view. I make the statement as to the *comparative* rarity of prostatic carcinoma advisedly, although it must be recognized as being far more common than was thought before the routine microscopic study of prostates removed at operation was undertaken by various surgeons.

As to the degree of obstruction ot which we should allow a case of hypertrophy of the prostate to go before counseling operation opinions differ; yet as we know the process to be a progresive one and as we know what a deleterious effect upon the patient's general health long continued catheter life, even in the absence of bladder infection, has, it seems to me that operation should be much sooner considered by the physician and surgeon than it generally is. We must not lose sight of the fact that practically all cases of catheterism finally end in cystitis, and that this in many instances is but the starting point of an ascending infection which finally terminates fatally.

Those cases which do not require the use of a catheter suffer the inconvenience of frequent micturition, especially at night, and with the progress of the malady become unfitted for either work or the enjoyment of leisure. In well marked cases the patients are a burden to themselves and to all about them, unable to keep themselves either clean or comfortable and certainly to be pitied.

Furthermore, we have a much greater chance of an operative recovery in a patient still in fair health than in one afflicted with cystitis or a retrograde kidney lesion and worn out by constant suffiering.

I would choose then, as the time of election for prostatectomy in cases of hypertrophy, that period in which the patient first begins to have distress, not delaying operation until all palliative and local measures have been tried and found wanting.

Doubtless in individual instances there may be considerations which might influence us to desist from operation. Severe heart or lung lesions might render anesthesia, even local, unadvisable or impossible. Age is not a bar to prostatectomy, provided the general health of the patient is good. Some of my most brilliant results have been in men over seventy and eighty years of age.

In thus setting the indications for prostatectomy it may not be amiss to remark upon one of the operations which came into the field before radical removal of the prostate was very common—namely, the Bottini operation.

I do not practise it any more. While in a very few instances it may be advisable, I consider it hazardous and unsatisfactory. The improvements in the technique of prostatectomy and the adaptation of various operations to the needs of individual patients have rendered the operation slightly, if at all, more dangerous than the Bottini, and there has never been any question concerning the relative value of the two methods of procedure among surgeons who have had experience with both.

As I have mentioned a short while ago, the clinical differentiation between carcinoma and hypertrophy of the prostate is far from being easy. Indeed, the vast majority of prostatic carcinomata are not diagnosed before operation. A tentative diagnosis of a prostatic malignant growth is warranted where we have progressive prostatic enlargement in a man rather below the usual age for prostatic hypertrophy and in whom the local symptoms are rather more grave than would seem to be warranted by the condition found upon examination. The most conspicuous symptoms are sacral and perineal pain, which is continuous and not alone associated with micturition. The pain may also be referred along the sciatic and anterior crural nerves. Should the prostate be extremely firm or very nodular our suspicions would be still further strengthened. Perhaps the most reliable sign of a carcinomatous involvement of the prostate is an invasion toward the rectal mucosa. That is to say, in prostatic carcinomata we often note a failure of the rectal wall to slide freely over the prostate gland.

I have mentioned the presence of gonorrheal prostatitis of the chronic variety as being sometimes an indication for prostatectomy. There is no doubt that certain chronic cases of gonorrhea in which the prostate is greatly involved are incurable as long as the prostate remains. While the large majority are curable by prostatic massage and other local measures, some are resistant to every form of treatment. It is, however, a difficult mater to decide when to advise a prostatectomy. Most men whom we see with this condition are not willing to pay such a price for the cure of their condition, involving as it may and usually does interference with normal sexual life. So that, while realizing that removal of the prostate is theoretically desirable, I believe it is often improper and impracticable to advise it.

Still another prostatic condition should be noted if we wish to take into consideration all the lesions demanding prostatectomy. This is tuberculosis of the prostate. The tubercular involvement of the gland is rarely if ever an independent condition. It is practically always associated with tuberculosis of other portions of the genito-urinary tract, especially the epididymis and bladder. Before undertaking any operation whatever on a tubercular prostate we should be sure that the associated organs are not so involved that operation will not do more harm than good, and that the patient is not the subject of tuberculosis elsewhere.

A mention of tuberculosis brings to mind another very important point in the discussion of the indications for prostatectomy. It is this—the frequency with which tubercular (and at times other) lesions of the genitourinary tract higher up give us symptoms referable to the prostate. Tubercular cystitis in its incipiency, and especially tubercular nephritis and pyelitis, in which there is always infected and more or less irritating urine being voided, at times give symptoms almost entirely referred to the bladder trigone and the prostatic urethra. This is not to be wondered at, especially when we bear in mind the peculiar sensitiveness of the floor of the prostatic urethra and verumontanum. I have lately had occasion to observe a case in which a tubercular kidney condition manifested itself primarily by symptoms referable entirely to the prostatic zone. A careful cystoscopic examination should always be made.

Granting, however, that a prostatectomy is for any reason considered advisable, what method shall we adopt for its performance?

We have the choice of two approaches to the prostate—the suprapubic and the perineal route. I have never used or found need for a combined suprapubic and perineal operation. Each mode of

operation has had its strenuous advocates, yet no surgeon would be doing his patients justice in selecting the operation who does not use both methods—each in its proper place.

In simple hypertrophy I at times use the suprapubic method, at others the perineal. A careful selection of cases for each is just as important as the proper performance of the operation itself.

The suprapubic route has certainly very definite advantages. It offers a free exposure of the gland, a comparatively large working area and few anatomical difficulties. It is, therefore, the ideal mode of approach for the removal of large prostates (soft adenomatous) and for these I always employ it. It is my uniform experience that the large adenomatous prostates may be far more advantageously removed by the suprapubic than by the perineal route. There is a larger working space and we are not compelled to remove the gland piecemeal. We know also that as a general rule hemorrhage is more apt to occur after the removal of a large prostate, which leaves a deep bed with a great bleeding surface. If the bleeding is excessive it is very easily controlled by packing, as will be spoken of further on.

My technique for the suprapubic prostatectomy is as follows: After preparing and anaesthetising the patient in the usual way, a catheter is introduced into the bladder and whatever urine is present is drawn off. The bladder is then washed out with a boric acid solution until the fluid returns clear. About four ounces of boric acid or normal salt solution are then introduced and the catheter clamped to prevent its escape. The patient is then placed in the Trendelenburg position. This causes the viscera to gravitate away from the bladder. The fluid contained in the bladder is sufficient to distend it enough, and in connection with the high pelvic position to raise the peritoneum to such an extent that we have in the median line an area of the bladder not covered by peritoneum. In other words, the bladder is opened extraperitoneally. Introducing narrow retractors laterally and posteriorly the base of the bladder, the prostate, and the catheter filling the urethral orifice are well exposed. A small incision is then made through the mucous membrane on either side of, or around the orifice of the urethra, and by means of the ungloved finger the prostate is shelled out, the finger finding a natural line of cleavage between the sheath and the true capsule. While this is being done the surgeon supports the prostate by one or two fingers of the other hand placed in the rectum, and so furnishes also a guide to prevent tearing into the rectum by the decapsulating finger. It may not be possible to remove the prostate entire, but as a rule we can do so. At times we are able to preserve the prostatic urethra, at others not. I have never noticed any difference in results whether this was done or not, with the exception that I think stricture is more likely to occur where the prostatic urethra has been removed. The bed of the prostate will always show some slight oozing, and after it is possible to secure hemostasis by the use of hot douche of saline or sterile water. When, however, there is the least doubt concerning the bleeding I pack the bed of the prostate with a strip of gauze, and when possible place a purse string suture of catgut in the bladder mucosa surrounding the opening.

We have now to complete the operation by taking care of the bladder wound and supplying an efficient means of drainage for the urine. The bladder may be stitched with catgut at either extremity of the wound, if this be very large. Into the bladder I place a large firm rubber tube of at least three-quarters of an inch in diameter open at the bottom and with the sides also fenestrated. It is introduced just a little way into the bladder so that drainage is not interfered with, and it is held in place by one stitch of catgut passed through the skin, superficial fascia and sheath of the rectus. The fascial layers and the skin are then stitched with catgut and one through and through suture of catgut passed through all the layers of the wound including the walls of the bladder, which serves to hold the bladder up. Unless this deep suture is put in, the bladder may prolapse away from the tube and fail to drain properly.

The operation being completed, the patient is removed to bed and the suprapubic tube is connected with a rubber outlet tube running to a receptacle, which contains an antiseptic fluid, at the side of the bed.

The operation as I have outlined it is in all its essentials the one popularized, but not originated, by Mr. Freyer, of London. I am accustomed to say to my students that the post operative treatment should begin before operation. That is, we should see that the patient's general condition is as good as it is possible for us to have it, and especially that his kidneys are functionating well. It is to be expected that in men past middle age with a tendency to arteriosclerosis some renal deficiency should be present, and it has been my experience that after these operations scantiness of urine and uraemia are the complications that we most often are compelled to meet.

On the table the patient should be placed on a hot water bed, or very warmly wrapped in blankets and should be protected both in the operating room and in transit to and from it from every possibility of a draft. Post operative pneumonia is not an uncommon occurrence in these cases, and is often given its start by the soaking and drainage of urine and fluids about the bed clothes of the patient.

Should gauze have been placed in the prostatic bed to prevent hemorrhage, it is best to leave it in four or five days so that in its removal we do not run the risk of secondary hemorrhage, yet we must not allow our caution in this respect to go too far. If the gauze be left a very long time it has a tendency to seriously retard the healing of the suprapubic wound and to contribute to the formation of a fistula. The drainage tube should be left in for from three to five days, and its fairly early removal is called for also to hasten healing of the wound.

After removal of the suprapubic tube the urine is left to drain freely into gauze pads, while every effort is made to keep the patient as clean as possible. I do not leave a urethral catheter in these cases as it performs no useful function, and may, and does, seriously interfere with the patient's comfort. I do, however, pass a sound at the expiration of about eight days after operation, and at least once a week thereafter until healing is complete. Stricture of the urethra after suprapubic prostatectomy is most rare, but is not unknown and should be guarded against.

Permanent fistula after the suprapubic operation is in my practice unknown. The wound heals at times very rapidly and as a rule the patients should

be well in from four to six weeks. Occasionally, by reason of the metabolism of the patient and the constant exposure of the bladder, there is marked tendency to the precipitation of phosphates, which are deposited around the walls of the fistula and cause delay in healing. The condition is a difficult one to treat, but may be improved by the use of large quantities of water internally, regulation of diet, and the administration of such drugs as urotropin and sodium benzoate.

The drinking of water is to be advised regardless of this condition. It serves to keep up the kidney function and to flush out the organs, and as I have already mentioned, the use of diuretics may at times be needed, as the kidney function is the one most difficult to keep at par after these operations. Both hypodermoclysis and proctoclysis are in some instances invaluable.

The patient should be fed liberally after the first few days, should be encouraged to sit up and gotten out of bed as soon as possible, and instructed to take advantage of any chance to pass even a few drops of urine by the urethral route.

There is but one serious immediate postoperative complication with which we may have to deal after a suprapubic prostatectomy—hemorrhage. It is exceedingly rare if the technique of the operation has been carried out carefully and with attention to detail, yet it does at times occur. The treatment consists first in the local application of hot solutions to the bladder by irrigation, and rest for the patient. At times the use of ice-bags externally over the bladder region seems to have a hemostatic action. Should these simple measures fail to stop the bleeding or reduce it to a slight oozing, we must reopen the bladder and firmly pack the prostatic bed.

A perineal prostatectomy I consider the operation of choice in all small and fibrous prostates, especially those situated low down in the perineum. There are several reason for this choice of approach. In the first place, we must traverse much less space to reach the gland itself. The anatomy is somewhat complex, but when once mastered it presents, even when pathologically altered, no very grave difficulties. If the prostate be very adherent to its outer capsule, removal by the suprapubic method may be impossible, whereas by the perineal it may be accomplished.

Carcinomatous prostates should also be removed perineally. Their firm attachment to the rectal wall has already been noted, and the same reasons for this choice of operation hold good as in the small firm prostates. The perineal route also offers us the only chance of performing a radical operation for cancer of the prostate, such as the one advised by Young.

Gonorrheal, tuberculous, and sarcomatous prostates should also be removed perineally. In the first two the possible bladder infection by the two wounds in the wall of this viscus during the suprapubic procedure offers us sufficient ground for not adopting it.

The technique which I follow is that of Young. I consider it preferable to the methods of perineal prostatectomy advocated by Watson and others because it gives a much better exposure of the bladder and especially of its posterior surface, and because it enables the use of the senses of sight and touch, and not merely the latter.

For this operation the patient is put in a high lithotomy position. An inverted V incision is made in the perineum, the fat pushed back, and after the insertion of a two-branched retractor the central tendon is divided close to the bulb and the membraneous urethra exposed. This is then opened upon a guide and, the edges of the urethra being held open, a special tractor is introduced into the bladder and opened. The prostate is now firmly drawn down and the posterior surface exposed. The rectum is held out of the way by a narrow retractor and the prostate is now fully exposed. By means of lateral incisions to either side of the urethra, it is now possible by means of blunt dissection to free and remove the lateral lobes of the prostate, and at the same time allow the urethra and ejaculatory ducts to remain uninjured. It is in that latter feature that Young's technique is so much superior to other perineal prostatectomy methods, such as Proust, and although the preservation of the ducts is not always desirable or possible, they certainly do no harm if allowed to occupy their normal position. An enlarged median lobe can, by a little manipulation, be brought out through one or other of the lateral openings without in any way injuring the ejaculatory ducts, except in particularly unfavorable cases.

When the operation is completed the lateral cavities are packed lightly with gauze. Two drainage tubes are placed side by side into the bladder through one limb of the incision, and the incision closed up to the drainage tubes, while the other incision is closed entirely. These two tubes serve the purpose of continuous irrigation of the bladder with saline solution when this is considered necessary to prevent blocking or even as a routine measure. It is my practice not to take out the gauze until the third or fourth day, the tubes being left in a day or two longer if they will remain. Sounds are passed at intervals of about a week, starting ten days after the operation.

Hemorrhage after a properly performed perineal operation is rare, but when it does occur prompt and thorough packing is the only method at our command worthy of consideration.

Fistulæ are more common after the perineal than after the suprapubic operation, and the chances of an operative cure are even less. On the other hand, they are probably less objectionable to the patient than the suprapubic, though the existence of either variety of fistula is enough to produce much discomfort to the sufferer.

The technique of both these operations I have sometimes varied slightly to suit the requirements of individual cases, but I endeavor in either one to keep as close as possible to the typical procedure. Within the last few years Young has described a radical prostatectomy for carcinoma. His method involves removal of the gland, resection of the bladder wall in proximity to it and transplantation of the urethra, and he has reported two at least temporarily successful cases out of four operated upon. I myself have never performed this operation. While in the hands of an experienced man it may be at times successful, it is too grave and complicated a procedure ever to come into general use. Its mortality and difficulty seem to me to more than balance its advantages.

From the description of the cases on which this method of prostatectomy is performed it is evident that it is an operation calling for considerable skill and care to be successful. Our cases must be properly selected and thoroughly prepared. The opera-

tion must be painstaking and exact and the after treatment carried out with continual vigilance. Yet when we consider the disadvantages under which it is often performed we can well say that a prostatectomy properly done is a satisfactory operation, usually entirely successful in relieving the patient and prolonging his life.

1634 Walnut Street.

A CASE OF ACROMEGALY WITH THROMBOPHLEBITIS OF THE SUPERFICIAL VEINS.

A STUDY OF THE CARDIOVASCULAR CHANGES IN ACROMEGALY.

By JOHN PHILLIPS, M.B.,

CLEVELAND, OHIO.

INSTRUCTOR IN MEDICINE, WESTERN RESERVE UNIVERSITY; ATTENDING PHYSICIAN TO THE DISPENSARY OF THE BABIES' DISPENSARY AND HOSPITAL.

This case of acromelagy is considered worthy of report because of the occurrence of thrombophlebitis of the superficial veins. In a careful search through the literature I have been unable to find a similar case recorded.

R. W., male, aged 51, Lakeside Hospital Medical No. 5685, was admitted to Lakeside Hospital May 28, 1906, on the service of Dr. E. F. Cushing, to whom I am indebted for the privilege of making this report. The patient complained of stomach trouble, swelling of the feet, and shortness of breath on exertion. The family history threw no light on the case. He had typhoid fever when eleven years of age, and rheumatism in the spring of 1905. Following his attack of rheumatism he had shortness of breath, weakness, and swelling of the feet, which persisted with some intermissions until his admission to the hospital. He had always used whiskey, beer, tea, coffee, and tobacco very freely. He had gonorrhea eighteen years previously, but had never had syphilis. On inquiry as to whether his hands and feet had become larger or his voice coarser in recent years, he thought that they had, though he was of such a low grade of intelligence that he paid little attention to these details. However, his sister, who came to visit him at the hospital and who had not seen him for ten years, said that he had changed so that she could scarcely believe he was her brother. She said his hands were very much larger, that he wore much larger shoes, and his voice was much coarser than when she had last seen him.

Fig. 1.—Showing the appearance of the patient when 28 years old.

Fig. 2.—Showing the appearance of the patient at the time of admission to hospital.

The illness for which he was admitted to the hospital began one year before with weakness and shortness of breath on exertion. He also had marked swelling of his feet. This condition continued with intervals of improvement until he was admitted to the hospital. At that time he had severe attacks of nocturnal dyspnea.

Physical Examination.—Patient was a large, heavily built man, height 5 feet 8 inches, weight 210 pounds. He stood with his feet quite wide apart, and his shoulders and head bent forward so that he looked from under his eyebrows. He answered questions readily, but his mentality was below normal. His face was massive, deeply wrinkled, especially about the forehead, his expression sorrowful, though he was quite good natured. His general musculature was quite well developed, but not in proportion to his massive size. The skin of his face was dark from exposure, and felt thick. His hair was very coarse, had a tendency to stand up, and the hair line came down low on his forehead. His head was round in shape; the external occipital protuberance stood out as a rounded prominence, the base of which was 3 c.m. in diameter and raised 2 c.m. above the surface. The superior curved lines of the occipital bone formed very prominent ridges. The glabellæ of the frontal bone were very prominent, owing no doubt to the enlarged frontal sinuses. The superciliary ridges of the frontal bone were much enlarged. The zygomatic arches were massive; the malar bones and the infraorbital portions of the superior maxilla stood out as large

prominences due probably to the enlarged cavity of the antrum. The nose was large and globular and the alæ were very thick; the hypertrophy affected chiefly the cartilages and soft parts of the nose. His mouth was large, the upper lip 1.5 c.m. thick, and the distance from the lower border of the nasal

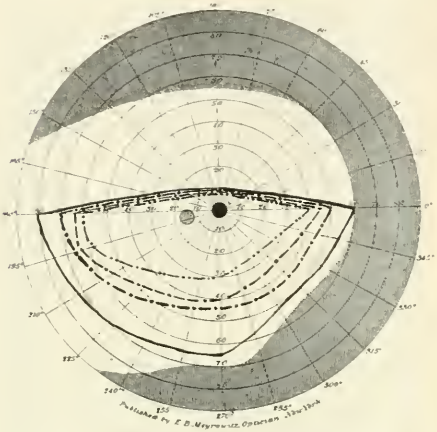

Fig. 3.—Fields of Vision in the Left Eye. Form outline, —; blue, . — . —; red, . — — . — —; green, . . — . . —

septum to the margin of the upper lip was 2.5 c.m. The lower jaw was large and projected forward so that in closing his mouth the lower teeth were in front of the upper. The teeth showed considerable decay and those in the lower jaw showed distinct spacing. The alveolar processes were 2.5 c.m. in width. The palate arch was very high, extending upward as a deep groove 2.5 c.m. wide and 1.5 c.m. deep, the deepest part being posteriorly. The tongue was dry, not coated, very large, with deep fissures on the dorsum, and the papillæ were very much hypertrophied. The tonsils were slightly enlarged, the epiglottis smaller than normal, and the vocal cords moved freely but were considerably thickened.

His speech was slow and the tone of his voice harsh and deep. His hearing was good; the lobules of his ears were very large. The circumference of his head measured 58 c.m., from the point of his chin to the hair line on his forehead 21 c.m. The examination of the eyes revealed nothing abnormal except the limitation of the visual fields (see diagrams).

His neck was large and very short. The thyroid cartilage was massive and the pomum Adami was very prominent and sharp. The thyroid gland was palpable but not enlarged. There was no general glandular enlargement.

The chest was barrel-shaped with a very marked cervicodorsal curve. The spinous processes of all the vertebræ were prominent and thickened, especially the spines of the seventh cervical and first dorsal vertebræ. The spinous processes of all the dorsal vertebræ were much lengthened. The shoulder girdle was massive.

The clavicle was long and broad, its curves accentuated, and much roughened at the site of the attachment of the muscles. The scapula was very broad and the spine, the acromion, and the coracoid process were rough, thickened, and enlarged. The costal angle was very obtuse. A broad shallow funnel-shaped depression was noticed over the lower part of the sternum. The manubrium sterni was broad and formed a sharp angle with the gladiolus. The percussion note over the upper part of the sternum was quite dull. On the left side at the costal margin in the mammary line a distinct bone deformity, the result of an old injury, projected 2.5 c.m. above the surface. The circumference of the chest was 101.5 c.m., expansion 1.5 c.m. His lungs were clear throughout to percussion and auscultation.

The point of maximum impulse of the heart was feeble, somewhat diffusely seen and felt in the fifth interspace just outside of the mammary line. The relative cardiac dullness extended to the left 14 c.m. from the midsternal line at the level of the fourth rib, and to the right 2 c.m. beyond the right sternal border at the same level. The first sound of the heart was very irregular both in force and rhythm, and at the apex could be heard a soft blowing systolic murmur, which was transmitted faintly into the axilla, but could not be heard in the back. The second sound in the aortic area was considerably accentuated. His pulse was irregular and arrhythmic, volume full, pulse rate, 66. The arteries accessible to palpation were all large and showed considerable sclerosis. The blood pressure was 170 mm. (Riva-Rocci instrument. Cook's modification, 10 c.m. band.)

The abdomen was quite pendulous. The growth of hair over its lower part was abundant but not unusually so. The spleen was not palpable. The lower border of the liver could be felt 3 c.m. below the costal border. There was no abdominal tenderness and no masses were felt. His penis and testicles were normal in size.

His hands were very large and spade-like in character, the increase in size being more marked in breadth than in length. The thenar and hypothenar eminences were very prominent and heavily padded. The skin of the palm threw itself into thick folds when the hand was closed, similarly when the fingers were extended thick folds appeared on the dorsum of the hand. The thumb was short,

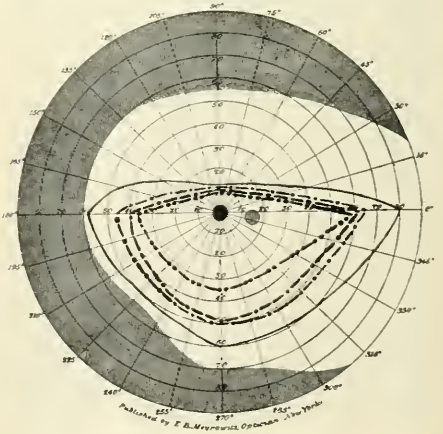

Fig. 4.—Fields of Vision in the Right Eye. Form outline, —; blue, . — . —; red, . — — . — —; green, . . — . . —

stood away from the index finger, and the dorsopalmar diameter was very long because of the thick padding of the ungual phalanx. The distal phalanges of the fingers were very thick, due to the similar padding of the palmar surface. The fingernails were large, shiny, and markedly curved, and

showed numerous linear striations. The fingers had a tendency to stand apart as though they were prevented from lying close together by the large size of the metacarphalangeal joints. When the wrist was tightly compressed a distinct flush of the hand unaccompanied by pain soon appeared, the veins being full and the arteries throbbing. This flushing was similar to that seen by the writer in a case of erythromelalgia in the same ward a few months before. The circumference of the palm of the hand was 25 c.m., of the wrist 18.5 c.m.; the length of the middle finger was 9 c.m., its greatest circumference 8 c.m. The musculature of the forearm seemed rather scanty when compared with the unusual size of the hand.

The feet showed changes similar to those described in the hands. They were very large so that he had to have his shoes made to order. The increase in size was chiefly in the breadth, the toes being short and thick with heavy padding on the

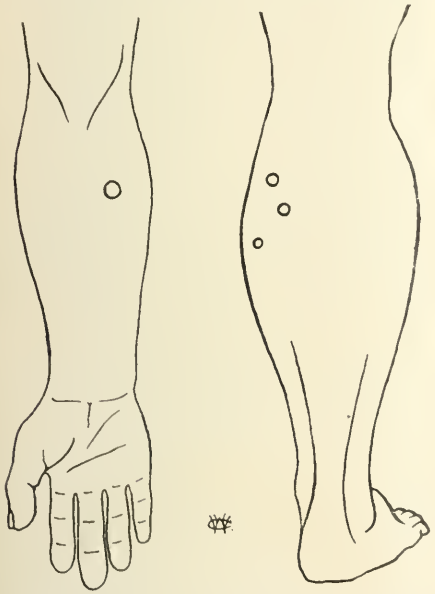

Fig. 5.—Showing the points of induration due to thrombophlebitis.

plantar surface. The great toe was extremely large. The nails showed marked trophic changes, being thick and markedly curved. When the feet were allowed to hang down with the patient sitting on the side of the bed, they rapidly showed a flushing brighter even than that described in the hands, with a similar dilatation of the veins and throbbing of the arteries. His patellar and Achilles tendon reflexes were present but sluggish. There was no disturbance in any part of the body of the sensation of touch, pain, heat, or cold. There was some edema of his shins.

His urine was scanty, highly colored, specific gravity 1024, reaction acid, albumin heavy trace, no sugar; microscopic examination showed an occasional leucocyte and epithelial cell, a few hyaline and granular casts.

The examination of the blood gave the following count: Red blood corpuscles 4,958,000, white blood corpuscles 6,800, hemaglobin (Dare) 80 per cent. The differential count of 500 leucocytes showed polymorphonuclears 51.5 per cent., small mononuclears 43.5 per cent., large mononuclears, 4.7 per cent., eosinophiles, 0.3 per cent. The red corpuscles stained well and were normal in size and shape.

With rest in bed and appropriate treatment his cardiac compensation was soon restored and his dyspnea and edema disappeared. During his entire stay in the hospital his skin was always bathed in perspiration.

The unusual feature of this case was the appearance in the middle of each forearm, eighteen days after his admission to the hospital, of small symmetrically-situated indurations. These were quite tender, 2 by 3 c.m. in size, and it could easily be determined that they were due to thrombophlebitis of the superficial veins. They soon lost their tenderness and disappeared in about ten days, leaving only a slight thickening. A few days later similar tender indurated areas appeared in each calf about midway between the knee and ankle joint. These also were definitely associated with the superficial veins. In all there were eight of these indurations due to thrombophlebitis. They were unassociated with rise of temperature or leucocytosis.

The patient died very suddenly a few days after leaving the hospital, and unfortunately an autopsy was not obtained.

Little attention has been paid by writers on the subject of acromegaly to the cardiovascular changes of this disease. In many cases hypertrophy and dilatation of the heart associated with arteriosclerosis have been described, but without comment, the writer apparently regarding the condition as a mere coincidence. Marie[1] mentioned the fact that syncope was a common cause of death in these patients and that they frequently had varicose veins.

Huchard[2] was really the first to call attention to the cardiovascular changes in acromegaly. He described three cases. In the first there were marked symptoms of angina pectoris. The second, a man 57 years old, seen fifteen years after the first signs of acromegaly developed, had cardiac hypertrophy with arrhythmia. The third case, a man 62 years of age, had all the signs of sclerosis of the heart with pronounced increase in the cardiac dullness, dilatation of the heart, and interstitial nephritis. Later his patient had breaking down of compensation, edema of the legs, and pulmonary infarction. J. B. C. Fournier[3] in 1896 in a thesis reviewed the literature of acromegaly up to that date and found twenty-five cases in which there were cardiovascular changes. Of the cases quoted by him the heart was enlarged in all except in the case described by Henrot. In this patient a man aged 35, the heart was small, the walls thin and flabby, but without any degeneration of the heart muscle. In Dallemagne's[4] case, quoted by Fournier, a man aged 47, who died from diabetic coma, the heart at autopsy weighed 885 grams. The wall of the left ventricle was 3 c.m. thick; the valves were not diseased except that the free edges of the mitral valve were slightly adherent. Histological examination showed an hypertrophy of the muscle fibers to double their normal size and a slight effacement of their striations, but without sclerosis or granular degeneration. The vessels showed thickening with yellow plaques of sclerosis and obliteration of the small branches of the arteries (endarteritis and periarteritis). In a second case recorded by Dallemagne the heart weighed 830 grams. Fournier divided the cardiac changes into two classes: (1) A simple en-

largement of the heart (cardiomegaly) without degeneration of the muscular fiber, the heart participating in the increase in size of the other organs (splanchnomegaly); (2) an hypertrophy in which there is a true sclerotic myocarditis, a cardiorenal arteriosclerosis often with enlarged liver, edema of the feet, albumin in the urine, and not infrequently angina pectoris. He attributed the arrhythmia to the direct action of the poison of acromegaly on the muscular fibers of the heart.

Klebs[6] attached a great deal of importance to the changes in the vessels. He found a great increase in the caliber of the vessels with thickening in the internal and external coats. In his patient, a man 40 years of age, the heart at autopsy weighed 550 grams; the mitral and tricuspid valves were insufficient. The vessels participated in this hypertrophy and dilatation.

The following are the measurements of the vessels, the figures noting the circumference of the vessels in millimeters: pulmonary artery outside the valves, 90; aorta outside the valves, 85; ascending aorta, 77; thoracic aorta under left clavicle, 60; intercostal arteries, 56; renal arteries, 36; lumbar arteries, 41; right iliac artery, 28; left iliac artery, 28; hypogastric artery, 18; external iliac artery, 24; femoral artery at Poupart's ligament, 20; deep femoral artery, 20; right subclavian, 34; right common carotid, 23; left common carotid, 23; right internal carotid, 26; right external carotid, 26; right vertebral artery, 14; thyroid artery, 10.

Tikomoroff[6] considered that the vascular lesions presented three stages, viz., (1) dilatation of the vessels, (2) thickening of their walls, (3) obliteration of their lumen. In some cases the vessels were transformed into fibrous cords. The thickening affected the media chiefly. In the various organs the walls of the vessels were thickened and dilated, sometimes causing hemorrhages through rupture. Furnival[7] reports a case of a man, age 58, with the usual signs of acromegaly. He was killed by a train and at autopsy the heart was found hypertrophied but no changes were noted in the valves. The kidneys showed an interstitial fibrosis. In discussing the pathological anatomy, the data for which was largely obtained from Sternberg's[8] Monograph, he says that the arteries are thickened and dilated, all the coats being affected by fibrosis, but especially the intima. These changes begin in the aorta and pulmonary artery and spread to the smaller vessels. The dilatation is probably secondary to the degeneration of the vessel walls, although Klebs maintained the contrary. The heart is generally hypertrophied and dilated, which is probably due to the changes in the blood-vessels. The kidneys are usually large and show signs of a chronic nephritis, the changes in the kidney being secondary to the cardiovascular lesions. In Hunter's[9] case, a male, 52 years of age, the heart weighed 26 ounces, showed general hypertrophy and dilatation, and the arteries at the base of the brain were very atheromatous. Claude and Moxter have also found marked arteriosclerosis.

At a meeting of the Association of American Physicians in 1897, O. T. Osborne[10] reported the clinical history and the autopsy findings in a patient who died at the age of 47 years from syncope. The heart was enormous, being 15 inches in circumference at the base of the ventricles and weighing two pounds and nine ounces. The wall of the right ventricle was three-eighths inch thick, that of the left seven-eighths inch. The valves of the heart were normal except for some slight thickening at the edges of the aortic valve. The coronary arteries were enlarged, admitting an ordinary lead pencil into their orifices. No occlusion of the heart vessels was found. In Leszynsky's[11] patient the heart was not enlarged and the arterial tension was normal, but four months later his heart action became feeble, albumin and casts appeared in the urine, and he developed a left-sided hemiplegia which was fatal. Labadie, Lagrave, and Deguy[12] have reported two cases with marked hypertrophy of the heart and arteriosclerosis. In one the heart weighed 1240 grams, and the radial artery was so sclerosed that it felt like a goose quill. Levi,[13] in a general review, gives among the symptoms of acromegaly, hypertrophy of the heart, arterial hypertension, and varicose veins. He summarizes the relation between this disease and the cardiovascular lesions as follows: The heart is hypertrophied, the aorta and pulmonary artery are the seat of thickening and dilatation; these alterations reach the ramifications of these trunks; as a result of a dilatation of the heart, the viscerae show the evidences of a stasis. Mitchell and LeCount,[14] in reporting the autopsy findings in a patient with acromegaly, whose heart weighed 450 grams and whose vessels were quite atheromatous, made an extensive review of the literature and found only eight cases, in which the condition of the heart was noted, in which enlargement was not found. Of these Hansemann found brown atrophy; Roxburgh and Coltes normal; Dallemagne atrophied (the same author reported two cases where the heart weighed 885 and 830 grams respectively); Henrot a curious atrophy of the heart and blood-vessels; Boltz, Frankel, slightly atrophied; Johnstone and Monroe, 225 grams.

The veins show changes similar to those described in the arteries. Varicose veins of the lower extremities are seen in nearly every case. It is easy then to understand the occurrence of thrombophlebitis as seen in the case here reported.

Whether the cardiovascular changes are a mere coincidence or one of the clinical features of acromegaly is the question to be decided. If the hypertrophy of the heart and the arteriosclerosis are due to the same cause as the changes in the bones, what is that cause? It is the opinion of the writer, both from a study of the clinical features of acromegaly and from the present physiological knowledge of the effects of extracts of the pituitary gland when injected into the circulation, that the cardiovascular changes should be considered as much a part of the clinical picture of acromegaly as the changes in the bones, and should be so recorded in our text books. The condition of erythromelalgia, which has been noted in acromegaly by several writers and was present in mild form in my case, is corroborative of this opinion, as Weir, Mitchell, and Spiller have shown that this condition depends upon an obliterative endarteritis of the vessels of the extremities.

In 1895 Oliver and Schäfer[15] found that injections of extracts of the pituitary caused usually a marked rise in blood pressure associated with an augmentation of the force of the heart beat. Szymonowicz[16] in 1896 in two experiments upon dogs obtained a slight fall of blood pressure and a quickening of the heart beat. In 1898 Howell[17] tested separately extracts of the anterior lobe and of the posterior lobe of the pituitary of the sheep by injection into the circulation of anesthetized dogs. He

found that extracts of the anterior lobe produced little or no perceptible change in blood pressure or heart rate. Extracts of the posterior lobe, however, in a dog with vagi intact, produced a pronounced slowing of the heart beat, together with an increase of blood pressure; while in a dog, with the vagi cut or under the influence of atropine, a prolonged rise in blood pressure was produced together with a stronger and slower heart beat. Magnus and Schäfer[18] in 1901 found that intravenous injection of saline extract of the posterior lobe is followed by a marked increase in the flow of urine. Schäfer and Herring[19] confirmed this observation and showed the striking parallelism which exists between the pituitary and the suprarenal bodies in development, structure, and functions. In each gland there are two parts, one of which, a highly vascular epithelium, yields an extract which is inactive; the other, of neuroectodermic origin, yields an extract which has a pronounced effect upon the heart and arteries. They advance the supposition that the epithelial part of each organ furnishes a secretion which passes through certain stages of formation, and that its production is merely completed by the neuroectodermic part, where the full activity of the secretion is acquired. Herring claims that there is histological evidence of the passage of this secretion into the third ventricle to mix with the cerebrospinal fluid. He claims that it is difficult to conceive that the posterior lobe of the pituitary should furnish an active secretion according to the usual views held of its structure. Cramer[20] has shown that strong extracts of the pituitary body produce within one or two hours a distinct dilatation of the pupil of the enucleated frogs' eye, but visible only after twelve or more hours with dilute extracts. The action of a solution of adrenalin on the pupil is more rapid but not so lasting.

Various theories have been advanced as to the essential cause of acromegaly. The majority of observers believe that the disease is associated with some alteration in the function of the pituitary body of which Rolleston[21] suggests three forms of modifications, viz., (1) suppression, a condition of incompetency of the pituitary analogous to myxedema or Addison's disease. Such incompetency would imply either an atrophy of the pituitary gland, which is not in accordance with the post-mortem findings, the reverse being the case, or else destruction by tumor; (2) hypersecretion, due to the excessive activity; this view is born out of observations of simple hypertrophy of the hypophysis. The administration of pituitary extract would be expected to aggravate the symptoms. However, I think that the action of the pituitary extract like that of the parathyroids can not always be depended upon, as its active principle may be destroyed in the preparation. (3) Perverted function due to heterogenous transformation of the structure of the pituitary body.

The pathological changes in the gland point quite strongly to the hypersecretion theory. Hypertrophy of the prehypophysis with increased vascularity and increase of the chromophile cells, or adenomata are the most frequent lesions. Brooks[22] found the latter condition at autopsy in his three cases. Atrophy of the gland has never been reported except in the single instance of Mossé and Daunic,[23] and only very exceptionally has it been stated as normal in size. Many observers have found sarcomata of the gland, but, as Brooks points out, these were probably adenomata, as it is difficult to distinguish the two conditions. In fact in his first case he diagnosed the condition of the pituitary as a sarcoma, until with further study and comparison with his other cases of the disease, he came to the conclusion that the growth was an adenoma. Further the long course of the disease, in many cases twenty or twenty-five years is not consistent with sarcoma, nor have metastases been described in any of the cases. The increased secretion of the prehypophysis in acromegaly is claimed by Brooks to act as a stimulus to the overgrowth of the connective tissue cells leading to changes in the vessels, overgrowth of bones, and enlargement of the viscera.

The condition of arteriosclerosis with hypertrophy of the heart can be explained on the theory of hypersecretion of the pituitary. As stated above the action of extracts of the posterior lobe of the pituitary on blood pressure is analogous to that of extracts of the suprarenal gland. Josué, Erb, Fischer, Klotz, and others, have shown that arteriosclerosis of the aorta extending even to the peripheral vessels can be produced in rabbits by injections of adrenalin. If the supposition of Herring is correct that the anterior or epithelial portion of the pituitary body furnishes the secretion, the production of which is merely completed by the posterior part, where its full activity is acquired, then hyperplasia or adenomata of the anterior lobe, such as is found in acromegaly, would increase the secretion to be activated by the posterior lobe and passed on into the third ventricle. The increased secretion would cause a continued rise in blood-pressure which would eventually produce arteriosclerosis with subsequent hypertrophy of the heart.

General Conclusions.—Enlargement of the heart, either simple or associated with a myocarditis, is the condition usually found in acromegaly. Sclerosis of the arteries and degenerative lesions affecting the walls of the veins, with dilatation and subsequent obliteration of their lumen, are constantly present. These changes in the heart and vessels should be considered as much a part of the clinical picture as the changes in the bones, and they are probably due to the prolonged hypertension of the vessels, the result of hypersecretion of the pituitary body.

FREE SUPPURATIVE PERITONITIS.*

COMMENTS ON RECENT DISCUSSIONS.

By A. E. ISAACS, M.D.,

NEW YORK.

SURGEON, BETH ISRAEL HOSPITAL.

In looking over the discussions on free suppurative peritonitis recently held before two of the foremost medical societies, the American Medical Association and the American Surgical Association, in their 1908 meetings, various recollections were brought to mind of incidents in my own experience. The opinions expressed, some in agreement, others at variance with those I had formed, naturally recalled the pros and cons of conclusions I had reached. The importance of the subject prompts me to add this contribution to the already voluminous literature on the subject, for this literature will be many times more voluminous before the questions under discussion will be settled. Evidently surgery is "yet in the making," and these discussions show the manner in which it is being made.

The discussions mentioned do not lay much stress on the first great division of opinion, the question as to whether the treatment of septic peritonitis should be operative or not. Naturally in a discussion entirely among surgeons this question would not have prominence, as it is generally conceded that the most successful treatment is operative. Yet many, especially in the ranks of the internists and exceptionally among the surgeons, take the opposite stand. Even in these discussions a surgeon puts himself on record[1] that "cases of general peritonitis should be left alone—there was no use of operating when too late, etc." He reports, "of the last 34 cases of general diffuse peritonitis 21 have been saved by this course," a mortality of 35 per cent. The only virtue I can see in this treatment is that his courage in carrying out his convictions furnishes us with the death rate in these cases when not operated upon. By what process of reasoning he holds to his opinion in the face of a 5 per cent. mortality by the Murphy method is not quite clear. He could hardly plead a different class of cases, as he is just as indefinite in his classification as Murphy, including every grade of the affection in one class variously designated as "general peritonitis," or "general diffuse peritonitis" which agrees with the similarly vague "general free suppurative" or the "general diffuse variety" of Murphy. To quote from the discussion as reported, "He thought that a combination of the Ochsner method with the Murphy drop irrigation * * * seemed to give the best grounds for hope. * * * All such patients should be put in the Fowler position and be starved until they were tided over," in which direction he does not say, but the results show that it is likely to be in either.

So much for the question as to whether operation is in order or not. Even the few facts mentioned here speak for themselves, operation is indicated, though as to every rule there are exceptions. But let us view the subject from another point of view. Are the results published by Murphy to be uniformly expected in all series of cases if Murphy's plan of treatment is carried out? "Dr. Murphy in closing said positively that every case of general perforative peritonitis if managed correctly should recover."[2] From quite an extensive experience with this condition I should say that I can not agree with this conclusion, yet Murphy presents facts from which his deductions seem reasonable, and if the latter are not correct there must be reason for it. In mentioning Dr. Murphy's work in this field I most earnestly join in the universal praise and commendation that has been extended to him, yet I am sorry that there is one weak point, and that is that he, as well as most others, makes no distinction as to the different grades or state of progress of the affection. He says "as expressing the extent of the process, the terms now in use are very much at variance." He speaks of the terms "free," "diffuse," "spreading," "general," as being used by different writers without uniform meaning, and then ignores distinctions as to extent entirely, differentiating only the "free peritonitis" as a whole from the circumscribed variety, which latter is not under discussion in his paper or here.

Peritonitides have various degrees of severity due to various causes and for statistical purposes, or purposes on which prognosis may be based, they may well be divided into classes of various degrees of determinable severity. The most available primary classification as applied to prognosis should be based on the extent of surface involvement, because, other things being equal, this is the most important element in the determination of the gravity of the condition. That is, it is the most important obvious element, which may be determined with a fair degree of accuracy, often even before and always at the time of operation. While "the impression as to the extent of involvement, gained at the time of operation, may be erroneous," it should nevertheless be sufficiently good to permit of the division of the condition into three varieties with distinctly different outlooks regarding prognosis.

Murphy's only classification "according to the condition of the peritoneum and the nature of the exudate * * * as diffuse septic and diffuse suppurative" is a distinction that can not be made until the course of the affection is observed and bacteriological examination made, and can not be applied as a preoperative indication or for classification from a prognostic point of view, nor does he present it as such or mention it in relation to his results. His differentiation as well as many other elements influencing the prognosis, such as location of perforation, resistance of patient, length of time from onset of infection, are to be taken into consideration and as far as available should be applied

*Read at a metting of the East Side Physicians' Association.

as further influencing the prognosis in the respective subdivisions based on the extent of involvement. Were this latter brought out in Dr. Murphy's statistics it would most probably be found that the bulk of his cases would be included in the first two classes of the three I shall describe.

As the classification of peritonitides according to the extent of the process has been so confusing, the three divisions are designated as 1st, 2d and 3d grades in addition to the descriptive terms of each, and I would rather use the grade numbers than the terms in referring to them. The condition in general I would call free suppurative peritonitis, "free" to distinguish it from circumscribed, and "suppurative" in contradistinction to serous. The term "suppurative" is better than "septic," because all are more or less septic and the degree of septicity is not apparent at once and therefore the term cannot be properly applied until after bacteriological examination or the course of the affection determines its character in that regard.

I have included under free suppurative peritonitis those cases in which a distinctly purulent exudate was found unlimited by adhesions and free in the peritoneal cavity. Cases with clear or turbid serum exudates about the local inflammatory focus are not considered. With few exceptions perforation has been present in these cases, but that the presence of perforation is not essential in the causation of the condition is borne out by the fact that in four of this series in which no perforation was noted, the colon bacillus was found in the abdominal exudate. This is confirmatory of the observation of most competent authorities that septic infection may be carried through the unbroken tissues when their normal resistance to bacterial invasion is reduced by inflammation.

The first grade, or local free suppurative variety, should include those where perforation of a viscus, or rupture of a preexisting abscess, or spread of the sepsis through the inflamed tissues has caused a noncircumscribed purulent peritonitic exudate in the region of the infection, which, in case it be appendiceal, might extend into the pelvis and possibly the left iliac region. This class should have no greater mortality, in fact a smaller mortality, than the circumscribed abscess cases, and if it be more fatal in the hands of some it is due to meddlesome and unnecessarily complicated treatment, as is well brought out by Dr. Murphy in his reference to prolonged anesthesia, washing the abdomen, voluminous and irritating drainage, etc.

The second grade, or the diffuse free suppurative variety, would include a similar condition except that a greater extent of peritoneal surface is involved, the purulent exudate occupying the pelvis and the abdomen below the level of the umbilicus, with one or both flanks. In this variety the prognosis is not so favorable yet these cases should, as a rule, recover.

The third grade, or the general free suppurative variety, would refer to those in which practically the whole peritoneal cavity is involved, the purulent exudate extending to the upper limits of the abdomen, involving the regions about the liver, stomach and spleen, as well as both flanks and pelvis. When I say "practically the whole peritoneal cavity," I do not mean that there need be a universal involvement. This can only be determined postmortem. But for practical purposes incident to our object, the classification as applied to prognosis, it is sufficiently definite to call a peritonitis "general" when the purulent exudate is found to occupy the greater cavity from the pelvis to its upper regions. This unfortunate condition is usually the result of undue delay, but not always, as it is sometimes found within 24 hours of the onset of symptoms of peritoneal infection.

In this third variety the mortality is high in spite of any sort of treatment, and I doubt therefore whether Dr. Murphy had many of these in his reported series. That seven had to be reoperated upon for secondary local abscess, and 6 for postoperative mechanical ileus, is hardly a criterion of the severity of the cases. Secondary local abscess may occur in cases of any degree of severity. My series includes two in the second grade and none in the third or severe grade. Mechanical ileus is a complication that occurs even in aseptic intraperitoneal work, and while it is to be expected oftener after peritonitis, it does not necessarily indicate the severity of the process. It was the cause of death in one of my cases classed in the third grade, though I have had it occur in clean and local abscess cases. The only other clue Murphy gives whereby to judge the gravity of his cases is the length of time after their first symptoms of perforation which he gives as from 3 to 40 hours, mostly from 22 to 30 hours, and which therefore would not be likely to include many of the bad class. In answer to the question as to how many of the cases were operated after 4 or 5 days after onset of the general peritonitis, and in how many cases death appeared to be imminent, Dr. Murphy said that he did not have any 4 or 5 days old and trusted he never would have. In how many death appeared to be imminent he did not say.

While time is not the only element in determining the gravity of a case, it is a very important one, and unfortunately comes into consideration more frequently than the surgeons would like to have it. Dr. Murphy lays stress on this point, and in fact assigns much of the credit for his good results to the family physicians who recognized the condition in time for early interventon, and well may he compliment them for a series of 50 cases with an average of 26 hours' duration.

The classification presented above is not intended as a sharp division even in reference to extent of involvement, for there can be no sharply defined lines, and the classes must more or less merge into each other at their points of division. Yet it is sufficiently definite to serve its purpose and would prove of great advantage if considered in reports on mortality. Neither is this classification presented as any sort of a systematic division in relation to the various causes and conditions that influence the result in these cases. Such causes and conditions are too many and various to be considered here. It is merely intended as a ready classification according to condition evident either previous to or immediately on operation, and as a basis on which to figure the mortality, so that such results as reported by Dr. Murphy and conclusions such as expressed by him, "every case of general perforative peritonitis if managed correctly should recover," be applied where they belong, to certain classes of these cases, and not to "general free suppurative" peritonitis as a whole.

Dr. Murphy's conclusions are drawn from his experience with a total of 51 cases of free suppurative peritonitis, unclassified as to severity, and arising from various causes, operated by him within five years of May, 1908, when his paper was read before

the American Surgical Association. Of these 51 cases, 42 were of appendiceal origin. The mortality in the whole series was but two, both appendiceal.

The criticisms and conclusions in this paper are based on a series of 66 cases of free suppurative peritonitis, all that occurred in about 220 appendicitis cases operated by myself within the past three and one-half years, that is, since July, 1905, when my last paper on this subject was presented. This series includes every case that came under my care during this period and submitted to operation. The great bulk were in my service at the Beth Israel Hospital, and the records are at the disposal of anyone sufficiently interested to see them. In no case was operation refused on account of dubious outlook or on any such plea as "discredit to surgery," a frequent convenient excuse for omitting to operate a bad case.

Of the total of 66 free suppurative cases of all grades, 10 died, a mortality of 15 per cent., though how unjust and misleading it is to charge up this death rate to free suppurative peritonitis in general is shown by the statistics of this same series of cases when divided into three classes according to their degree of severity as indicated by the extent of involvement of the peritoneum.

There were of the first grade, or local free suppurative, 20 cases with no mortality. Of the second grade, or diffuse free suppurative, 27 with one death, or a mortality of less than 4 per cent. Of the third grade, or general free suppurative, 19 cases with 9 deaths, a mortality of 47 per cent.

While the first grade has practically no mortality, and the second a very low one, the third has a high death rate in spite of any sort of treatment, because in many of this class, besides the usual difficulties and dangers that may be overcome by operative treatment, complications have already developed that are beyond relief through drainage of the abdomen, though they be due primarily to infection from that source. It will be interesting to note Dr. Murphy's further experience and see if the probabilities of averages will come true; his cases averaged 22 to 30 hours' duration, and he has not had any of more than 40 hours, and hopes he never will have, a desire that we all share, but in the realization of which we have not been so fortunate.

In 1900, Dr. G. R. Fowler reported 12 successive cases with no mortality which he attributed to the mode of treatment he then advocated, and especially to what we now call the Fowler position. In 1904, by the time the series reached 100, he and Dr. R. S. Fowler reported a mortality of 33 per cent.

The results of operation will improve as the proportion of bad cases diminishes, which will take place as the laity lose their prejudice against operation and the general practitioner learns to recognize the condition as soon as it occurs.

It is peculiar how cases will run. My series begins with 12 consecutive recoveries, then one death and again 12 recoveries, making 25 cases with but one death, a fair number on which to have based a report of a 4 per cent. mortality. But this was evidently due to coincidence, as the results, good or bad, of any small series are likely to be. The average proportion of bad ones must come in sooner or later, and they did in my series in this wise: the 26th and 27th died. Then there were 15 recoveries up to case 43, which died. Then 3 recoveries followed by 2 deaths, 1 recovery by 1 death, 4 recoveries by 1 death, 3 recoveries by 1 death, 1 recovery by 1 death, leaving the last 5, which were recoveries.

In the latter part of 1906, about the time Dr. Murphy read his former paper in which he surprised the profession by reporting thirty-six cases of "general suppurative peritonitis" with one death, I was making the record above mentioned on the first twenty-five cases of this series. My plan of treatment was similar in all its essentials to that then presented by him, and had been in use for a couple of years in my service at the Beth Israel Hospital. I had been using as little anesthetic as possible, been making operation as brief as possible, had discarded flushing of the cavity, extensive incisions and voluminous drainage, especially of gauze, and had been leaving only small openings for rubber tissue drains, all of which was discussed in a paper published in 1906,[3] which covered a series of cases operated up to June, 1905. Proctoclysis was given by frequently repeated small rectal installations in place of the continuous infusion which I now prefer. The results were so excellent that I wished to add my testimony to his eloquent plea for simplicity in the operative treatment of this condition. But the paper I began to write did not materialize at that time and I now have the opportunity of reporting a much larger number of cases, with a higher mortality when considered as a class, but no higher when the character of the cases is taken into consideration.

I have attempted to gather from recent literature the mortality rate of various surgeons within the past few years since the new plan of treatment has been generally accepted. In 1906 I find Gibbon[4] and Ross[5] each reporting 8 cases with mortality of 37 per cent.; Robson[6] 6 cases with 17 per cent.; Morton[7] 20 cases with 35 per cent., though he divides his cases in the manner I advocate, but only into two classes, diffuse and general, there being 14 of the former with 2 deaths and 6 of the latter with 5 deaths. In 1907 Moynihan[8] reports 19 cases with 10 per cent. mortality, Douglas[9?] mentions no number but reports a mortality of 50 per cent. and says Mayo admits the same. In 1908 McGuire[10] reports 24 cases with 25 per cent. mortality, Katzenberg[11] 27 cases with 7 per cent., though he uses flushing of the cavity but no wiping. R. H. Fowler[12] reports 69 cases in the service of Drs. Curtis and Gibson at the St. Luke's Hospital in the nine and one-half years previous to 1908. He calls them cases in which the entire greater sac was involved, yet his description only "excludes from this series all lesions which might possibly have been interpreted as spreading processes, by which is meant an inflammation located in one quadrant or half of the abdominal cavity." This would exclude the first grade of my classification and include the second and third. The whole series gave a 69 per cent. mortality. The 25 cases of 1905, 1906, and 1907 gave 50 per cent. mortality. The treatment included flushing, multiple incisions, and rubber tube drains. Eisendrath[13] gives the results by twelve surgeons "obtained at the large American and European hospitals." They comprise 12 series, ranging each from 13 to 65 cases and give mortalities of from 17 to 80 per cent., averaging 50 per cent.

Eisendrath also reports 34 cases from the Michael Reese Hospital, occurring during the past nine years of which the general mortality was 41 per cent. But he also recognizes the injustice of lumping all cases in one class and subdivides them into

three grades of severity, basing his division on the duration of the affection. In 26 of the cases where this was noted, of 10 operated upon within the first 24 hours, the mortality was 1 or 10 per cent.; of 10 operated upon within 48 hours, mortality was 2 or 20 per cent.; and of 6 operated upon on the third day the mortality was 2 or 33 per cent. Korte, one of the surgeons quoted by Eisendrath, also makes a like distinction, reporting 27 cases operated upon within the first 48 hours with a mortality of 18 per cent., and 30 operated upon on the third day with a mortality of 36 per cent. This attempt at classification is a step out of the general maze, but hardly in the right direction, as the classification based on the extent of involvement is preferable for reasons already mentioned.

The manner of treatment brought out quite some differences of opinion. Drainage came in for a good deal of discussion. The ultraprogressive enthusiasts who wash out the pus and close the abdomen, sometimes with oxygen gas, don't seem to have been represented. Those present seemed to agree on drainage, but differed considerably on the best manner of securing it. One preferred gauze to tubes. One placed the patient on the side to secure better drainage. Most agreed on the advantages of the Fowler position, though one reversed the position to the Trendelenburg and obtained good results, in two cases with persistent vomiting.

The claims for the efficacy of the Fowler position are based on the theory that gravity will bring the intraabdominal fluids down to the pelvis, where the anatomical structure and physiological action of the peritoneum are much less favorable to absorption, and from where they can be drained more easily, as the incision is usually in the lower abdomen. This is correct, but even in the prone position the same will happen, the exudate will find its way into the pelvis. The appendix lies as a rule on the elevation formed by the psoas muscle as it crosses the brim of the pelvis. This region, in the prone position, is about three inches higher than the most dependent portion of the pelvis and four inches above the bottom of the flank.[14] There must be some other reason besides gravitation why the fluid invariably finds its way first to the pelvis, for if gravity were the only element causing its spread it would just as likely flow down the other side of the "divide" and involve the right flank first, especially if the perforation would take place in the distal end of an upturned appendix. I do not recall to have observed this in any case, and if it does happen it is exceptional. It must be remembered that the peritoneal cavity is not to be compared to an empty vessel in which fluid would immediately find the lowest portion. On the contrary, it is a cavity only in the sense that the anatomical structure of its walls differs from that of its contents. It is filled with its viscera and has no empty space at all, and fluid exuded among its organs is under the tension of the intravisceral pressure, and the position and migration of the fluid depend not nearly so much on gravity as on other forces. Intravisceral tension may be sufficient to oppose gravity for a time, though eventually it will probably be overcome by the latter. Peristalsis may act likewise. The folds and attachments of the mesentery and of the mesocolon, forming ridges and gutters within the anatomical peritoneal cavity, also serve to deviate the advancing line of invading fluid from the direction it would otherwise take.

As a rule, the cases in which we operate have not been in the Fowler position previous to operation, yet what are the conditions we find? In a very recent case, due to perforation of the appendix, the fluid, though free, will be found in the region of the perforation only. In one somewhat more advanced it will be found spreading downward into the pelvis. At a later stage the pelvis will be full of fluid which will be found spreading up into the left iliac region. We do not find it spreading upward above the iliac regions or into the flanks unless the pelvis is involved first. If the primary infection always took place on the pelvic declivity of the "divide" we might ascribe to gravity alone this tendency of the fluid to invade the pelvis. But it undoubtedly takes place higher up in some cases where gravity unopposed would carry the fluid into the flank unless the body were elevated to an angle of over 51°. This amount of elevation would be necessary to bring the bottom of the flank on a level with the "divide," and 60° or more would be required to drain the flank properly by gravity.[14] This exaggerated Fowler position is hardly used, yet the patients drain and get well—they even get well in the prone position which I used for a time experimentally. I do not mean to minimize the importance of the Fowler position, for there can be no doubt that bringing the pelvis to a comparatively lower level favors gravitation of the fluid, makes the patient more comfortable, and is therefore a beneficial measure, but to place too much reliance upon it may result in neglect of other necessary measures, especially those directed toward securing efficient drainage. There is another reason why the Fowler position is beneficial, which I called attention to some years ago, but have not seen noted since. The more upright the position of the body the more the weight of the intestines forces them into the pelvis. This effect of gravity on the intestines in an open abdomen is seen and taken advantage of by every surgeon in the use of the Trendelenburg position in pelvic work. The weight of the intestines thus helps to displace any fluid that may accumulate in the pelvis and force it in the only direction in which it is not opposed, out through the drainage opening.

The tendency of the intestines is to adapt themselves to and fill in all the available space within the abdominal walls. The expansive effect of their contained gases distends these elastic viscera to the extent permitted by the limits of the cavity containing them. When a portion of the cavity's space is occupied by fluid this expansive effect acting against the fluid will tend to displace it if it have an outlet through which it may be displaced. The result is that there is a continuous expulsive pressure on any fluid in the cavity, and there being an outlet, be it in the direction of gravity or otherwise, the fluid will be forced out through it. Other factors that assist in this expulsive intraabdominal force are the excursions of the diaphragm with every respiration, that add a sort of pumping effect; contractions of the abdominal muscles, as in coughing, straining or moving, act similarly; the Fowler position assists by adding the weight of the intestines as mentioned above.

This expulsive force of the intestines explains why an intraabdominal abscess or a collection of fluid in any part of the abdominal cavity will drain upward through the anterior abdominal wall almost as well as through a dependent lumbar or pelvic opening, if proper means to permit of drainage are used; why large and multiple incisions and bulky

gauze packings are not necessary for satisfactory drainage of the abdomen, as they may be in other regions of the body; and one reason why an extensive diffuse peritonitis may be drained through a very small incision situated almost anywhere within its area. It explains why in cases of circumscribed abscess, be it appendicular, perinephritic, pelvic, or any other within range of the effects of the distensible hollow viscera, a large cavity may become almost obliterated within a very short time after the pressure of its own accumulation is released by incision, though in this class of circumscribed abscess cases there are other factors, such as adhesions and rigidity of the walls of old abscesses, that retard and delay those effects.

In operative interference the primary object is to give an outlet to the confined septic fluid, and the secondary but just as important one is the establishment of satisfactory drainage to release such of the remaining fluid as will not be absorbed, as well as such as may be newly formed, and so obviate reaccumulation. The incision provides for the first requisite, and for reasons stated it need not be extensive. If removal of an offending organ, or reparatory work on damaged viscera, require a larger incision, it should be closed again to within the small limits necessary for abdominal drainage.

The manner of drainage is a very important item. An ideal drainage tract in the abdomen would be an opening that should retain its patency so long as there is anything to drain through it, and toward this object any measures used should be directed. The claim is put forth by many, especially those who advocate closure of the abdomen, that drainage of the peritoneum is useless because it does not drain. This observation is often true, and why drainage does not drain, as frequently employed, will be evident from further remarks. If used on the lines of known physical principles and with an appreciation of the difficulties to be overcome, abdominal drainage can be made satisfactory, sufficiently satisfactory to obtain the object sought, the provision of a sort of safety valve for those cases, indistinguishable at the time of operation, that will require it, while those whose subsequent course proves that they don't require it will not suffer any harm by its use.

The natural tendency of peritoneum covered viscera is to circumscribe any local irritant or infection by the formation of adhesions about it and so wall it off from the general peritoneal cavity. For various reasons this process is not efficient or does not take place soon enough in some cases, with the result that the infection spreads and produces a diffuse or general peritonitis. But even in a diffuse infection the tendency to spreading is overcome by release of the purulent accumulation through incision. The bulk of the fluid is discharged and the protective adhesive inflammation now has a chance to get in its good work and localize what remains of the infectious material which usually gravitates into the pelvis when that region is involved. Were no means used to secure the patency of the opening this adhesive interviscera inflammation would shut off the infectious material from the external opening and possibly result in reaccumulation. The requisites therefore are to overcome this tendency of adhesion in the line of the drainage tract and to prevent closing of the abdominal opening.

For reasons already gone into, all that is necessary to secure abdominal drainage is an outlet from the region to be drained to the external surface. To restate the reasons briefly, they are that the distension of the hollow viscera and the pumping effect of the movements of respiration, etc., furnish the *vis a tergo* which forces the fluids out. But the outlet must remain patent and therefore some means must be used to prevent adhesions along the drainage tract. The ideal method of accomplishing this would be the interposition of some non-irritating substance that would keep the viscera from coming into contact along the desired tract, and at the same time would not become adherent to the viscera. What answers these requirements more nearly than anything I know of its guttapercha tissue; it is non-irritating, soft and flexible, and does not adhere to the serous surfaces. Folded into a strip from one quarter to three quarters of an inch wide, and of six to twelve layers in thickness to give it body, or wrapped about a strip of gauze, making the familiar "cigarette drain," it is the most satisfactory abdominal drain I know of. In the "cigarette" the effect of the gauze is to give body and consistency to the drain and not, as usually understood, to drain by reason of its capillary action.

Tubes of rubber or glass are often used with advantage, but it is an oft repeated observation that they do not drain through their lumen. The openings, terminal and lateral, become choked up by omentum or exudate or by the visceral walls, and when they do drain under these conditions the drainage takes place about the outer surface of the tube, in the same manner as when a strip of guttapercha tissue or a cigarette drain is used. The tissue strip, therefore, acts just as efficiently and without the disadvantages incident to tubes. A tube implies a rigid body likely to cause pressure necrosis on the delicate viscera, whereas a strip of tissue is pliable and will adapt itself to its environment. If the tube be of rubber its chemical structure is irritating to the tender serous membranes, and if of glass it is likely to be broken. In either case if perforated it may injure the viscera on withdrawal by pulling on the parts engaged in the perforations.

Gauze has been used, and is yet by many, on the theory that by reason of its capillarity it will soak up the fluid from the cavity and discharge it into the dressings. What it actually does is to excite a plastic exudate from the serous surface with which it comes in contact, which exudate works into its mesh and glues it firmly to the peritoneal surface. Then the fluid which it soaks up, in place of proceeding to the dressings, stagnates on the gauze by reason of its viscidity, chokes its capillarity and causes a condition that would be ideal if the object were to plug the opening. These qualities of gauze are rightly taken advantage of for the control of hemorrhage, and its action under these conditions is a good illustration of why it will not act as a drain under conditions that are essentially similar. I do not know of any more efficient obstruction to drainage when the amount of discharge is not large or when the size of the drainage tract is within reasonable limits. When the discharge is abundant and the opening large the abscess will drain in spite of the gauze as its volume and tension will force it past the obstruction in the same manner that such a packing would fail to control a free hemorrhage. Gauze would probably drain if the fluid to be acted on were water but where we have to deal with a more or less viscid fluid with a fair amount of solid residue in suspension to choke

the mesh, gauze drainage is a delusion and a snare. It is unsatisfactory because it does not drain; harmful because when used in small openings it obstructs drainage, and to leave large openings conduces to postoperative hernia; harmful also because the irritation of its presence results in more extensive adhesions, and because the gut by its agglutination to the gauze may be injured or displaced in its removal. It is uncalled for because all the objects sought through its use may be attained much more satisfactorily, and without the disadvantages mentioned, by the use of guttapercha tissue as described.

There are many more items of interest in the discussion I have attempted to review, but to consider more of them at the present time would make this paper too lengthy. I will close with brief reference to the main points in the method of treatment employed in my hospital service. There are no hard-and-fast rules; each case is treated on its merits. The usual procedure is as follows:

Anesthesia is begun after all preliminaries are attended to and the surgeon stands ready to make the incision. As little as practicable of the anesthetic is given. Local anesthesia is occasionally used. Incision is median for appendical cases. The operator proceeds with the idea of getting through as quickly as possible.

Excision of the appendix, or repair of other offending organ, ignoring the presence of exudate which is left to run out or to be absorbed by pads used in the course of the operation.

Exploration for fluid by two fingers passed along the anterior parietes into the pelvis, which at the same time serve as a guide for the introduction of the drain. Rinse hand and explore the left flank and drain if necessary (the right has been explored in removing the appendix). If sufficiently suspicious, likewise explore both right and left hypochondriac regions. All this exploration and placing of drains is done in a moment.

Drains should be of guttapercha tissue, either in folded strips or wrapped around a loose core of gauze.

Suture abdominal wall, preferably in layers if the case is not desperate, leaving only a small drain outlet. Drain the parietal wound.

Lavage of stomach while patient is coming out from the anesthesia.

Fowler position, moderate, if not uncomfortable, or if not contraindicated for other reasons.

Murphy rectal infusion. Stimulants hypodermically only as necessary. Opiates only if urgently called for. Calomel, in fractional doses, with saline on second day, followed by an enema if necessary.

Drains shortened or removed on the second or third day, or allowed to remain one or two weeks or longer according to conditions.

DANGER SIGNALS IN INFLAMMATION OF THE EAR.*

By WALTER A. WELLS, M.D.,

WASHINGTON, D. C.

PROFESSOR OF LARYNGOLOGY AND OTOLOGY, GEORGETOWN UNIVERSITY

THE formidable disturbances which we have in mind in connection with aural inflammation, occur almost exclusively in the suppurative form of otitis. Occasionally grave complications, including mastoid abscess and even brain lesions, are reported as accompanying nonsuppurative inflammation of the ear. It is my opinion that, in almost if not quite all of these cases, pus has really been present in the tympanic cavity, and has merely escaped observation. However this may be, the practical point worth remembering is that serious complications may develop in inflammations, where, at least, there is no history of a discharge.

The great preponderance of our ill-fated cases, however, are discharging ears, and the process consists of a suppurative inflammation affecting the middle ear. It is possible for the trouble to begin in the external ear, but no serious results will follow unless the middle ear has become involved. Disease of the internal ear can easily infect the cranial cavity, but inflammations of the internal ear are secondary to middle-ear inflammations.

The one invariable antecedent, therefore, is inflammation of the middle ear, of a suppurative character, which in all but a few instances will manifest itself by a discharge appearing at the external meatus.

A suppurative ear is very generally considered by the laity as only a trifling matter, and I fear that not even the medical profession entertain a view of its seriousness that is justified by a bare contemplation of the statistics.

To cite a few examples: Of 40,073 autopsies made from 1873 to 1894 at the Vienna General Hospital, Gruber found that aural suppuration was responsible for the death in 232 cases, or one out of every 173. A record of 9,000 consecutive autopsies at Guy's Hospital, London, showed 57 deaths as due to suppuration of the ear, which is a still higher proportion, viz., 1 to 158.

The frequency of intracranial complications in ear disease can be gathered from the New York Eye and Ear Hospital reports. Out of 65,000 cases of ear disease of all kinds treated at this hospital, 10,323 had discharging ears. Of this number it appears that severe intracranial complications occurred in 218, or 1 in every 88 cases. In a review of 12,744 cases of suppuration seen at the Manhattan Eye and Ear Hospital, Harris found that 60 of the patients suffered from meningitis, 23 from sinus thrombosis, and 7 had abscess of the brain.

Other serious troubles besides intracranial diseases may occur as a result of inflammation in the organ of hearing. The facial nerve as it traverses the tympanic cavity is covered by a very thin wall which may be eroded in the course of an inflammatory process. In some cases this wall is even lacking in places, easily exposing the nerve to injury. The result of such an accident is a disfiguring facial paralysis, which may or may not disappear, depending upon the nature of the lesion causing it.

The carotid artery and the bulb of the jugular vein are both at places dangerously close to the tympanic cavity and instances are not wanting of

*Read before the Fairfax County Medical Society, Falls Church, Va., November 5, 1908.

fatal accidents resulting from involvement of these vital structures.

An extension of the middle-ear inflammation inward to the labyrinth is necessarily a matter of the most serious import, for even if the trouble should proceed no farther, involvement of the cochlea and semicircular canals will produce a profound deafness and a vertigo sometimes so severe as to incapacitate the individual. Furthermore when there is a suppurative inflammation in this part of the auditory organ, the chance of infection of the intracranial contents is always imminent. Fortunately the internal ear is quite resistant to infection, so that it is only seldom we have this complication to fear.

It is especially in a backward direction that the inflammatory process is inclined to travel, attacking the mastoid antrum and the accessory cells situated in the mastoid apophysis. As the brain complications of middle-ear suppuration seldom occur except through the intervention of a preceding mastoiditis, the latter must naturally be regarded from this standpoint as a formidable complication. With the occurrence of mastoiditis the "danger line" is passed and from now on a watchful eye must be kept upon every symptom in order that no danger signal shall be overlooked. Involvement of the mastoid greatly increases the area of inflamed territory which is in relation with the intracranial contents.

The roof of the antrum is continuous with the roof of the tympanic cavity, the whole consisting of a very thin fragile plate of bone, forming a part of the floor upon which rests the temporal lobe of the brain. The posterior wall of the antrum, besides, is in relation with the sigmoid sinus and the cerebellum, so that we have here an additional danger point, through which infections might be carried to these structures. One of the serious features of mastoid involvement is that the focus of infection has now arrived at a locality where drainage conditions are peculiarly unfavorable. The pus imprisoned in the labyrinth of cells contained within the mastoid process has no outlet except through the antrum, which is the very uppermost cell communicating with the tympanum by way of a little channel called the aditus. Sometimes this passage becomes blocked by thickened secretion, so that the purulent contents can find no exit except by breaking through one of the cell walls.

Unfortunately for the patient, the wall which separates the antrum from the cranial viscera, is much thinner than the cortex or outer wall of the mastoid so that a rupture inward is more easily effected than one outward. Sometimes, indeed, as a result of faulty development the roof of the antrum or of the tympanum may actually be defective in places, leaving more or less wide openings in the bone, which form inviting gateways of infection.

In children the petrosquamous suture is probably an important way of infection. It is filled with soft tissues through which pass numerous veins connecting the middle ear with the cerebral structure.

Intracranial complication may occur with either acute or chronic suppuration of the ear, but with considerable greater frequency with the latter than the former. Chronic recurrent suppuration is to be regarded with the greatest suspicion, for it is especially in acute exacerbations of an old chronic discharge that the most frequent complications arise.

The intracranial complications against which we have to be on our guard are: (1) Pachymeningitis, with or without an epidural abscess. (2) Leptomeningitis, serous or purulent. (3) Abscess of cerebrum or cerebellum. (4) Sinus thrombosis.

Pachymeningitis, with a collection of pus on the surface of the brain, is one of the commonest, but fortunately the least fatal of the complications with which we have to deal. It occurs generally as a result of the direct inward extension of the suppurative process in the adjacent bone. The meningitis is usually localized and it is due to the fact that adhesions form between the membrane and the bone that the pus does not extend over a wider area.

Diffuse leptomeningitis, especially the purulent form, is the most dreaded of all the intracranial complications which can arise. In the textbooks it is, in fact, generally considered as hopeless and its development is considered by many surgeons as contraindicating operative interference. This pessimistic view has been modified by the report of a few undoubted cases in which recovery has taken place. I have recently in my own practice had such a case. The diagnosis, clear enough from the clinical course, was still further confirmed by a lumbar puncture, revealing pus in the spinal fluid. In this case I trephined the mastoid and opened the lateral sinus. The latter was found free of clot, but the mastoid was found diseased, and I think the cure may be attributed in a great measure to the complete eradication in this case of the focus of infection.

Brain abscess is a complication which with but the rarest exception will have a fatal termination if left to itself. The most frequent seat of the abscess is in the temporal lobe, in close proximity to the middle ear. Sometimes it is deeply situated and inaccessible at the time of operation.

Sinus thrombosis. A large venous channel carrying waste blood from the brain courses immediately in the rear of the mastoid process to continue downward into the jugular vein and thence directly to the right chamber of the heart. Suppurative disease involving the bone in this locality, not infrequently extends to this vein producing an infective thrombosis. Portions of the clot when detached and thrown into the circulation give rise to metastatic abscesses in all parts of the body. Surgical measures often prove successful in this complication, but a favorable outcome is gravely imperiled by waiting until septic phenomena have arisen.

Symptomatology.—It is foreign to the purpose of this paper to enter into a detailed discussion of the semiology of the complications of middle-ear inflammation. Fine points in the examination of the ear upon which the specialist depends very much in coming to a final conclusion will be avoided. Only general clinical symptoms and tests which are at the command of the general practitioner will be dwelt upon. These may not be sufficient for a differential diagnosis, but they constitute all that is needed; important danger signals which show at least that serious trouble is ahead, which prompt and intelligent action may successfully circumvent. Too much stress cannot be laid upon early recognition of these troubles.

When delirium, coma, paralysis, etc., have developed, a lesion of the brain may be easily diagnosed. But diagnosis at this stage is no credit to the physician and is probably too late to be of service to the patient. It is the discerning watchfulness for the early symptoms that counts, and this duty falls most often upon the general practitioner.

Let us then briefly consider the most important danger signals and their significance.

Pain.—Earache is an almost invariable symptom of acute inflammation of the middle ear, especially when suppuration takes place. In uncomplicated cases, the pain ceases promptly upon a rupture of the drum, which gives free outlet to the secretions. Continuance of the earache, therefore, after the discharge has set in is an unfavorable omen and leads us to suspect trouble.

When the mastoid cells are involved the pain is usually quite severe and is felt always just back of the ear and generally in the temporal region. There is often severe pain extending over the entire half of the head corresponding to the ear inflamed. A distinctive feature of the headache of mastoiditis is the tendency to become intensified during the night, so that the patient is unable to sleep unless quieted by opiates.

Excruciating cephalalgia occurring night and day suggests meningitis. The pains are then often of a paroxysmal character, augmented by motions of the body, and associated with points of tenderness over the scalp.

The capital symptom of acute mastoiditis is pain elicited upon pressure over the mastoid process of the temporal bone. A slight tenderness is sometimes noticed in the mastoid tip due to hyperemia of the mastoid cells, but it soon disappears if the process stops short of suppuration. Persistent tenderness, however, over any part of the mastoid process is a symptom full of significance.

One should be careful, however, not to confuse with mastoid tenderness that which is due to inflammation of the external ear, and which manifests itself only when the auricle is moved. To distinguish from this, make direct vertical pressure over the mastoid, avoiding contact with the auricle.

Swelling.—It is a common error to consider swelling over the mastoid as the index of what is going on beneath; to think, for example, that we are safe so long as no swelling exists and that a large fluctuating swelling is an alarming symptom calling for immediate operation. On the contrary, the most dangerous cases are those unattended with any external swelling. When the cortex of the bone is very thick, no swelling will take place, and the chances are accordingly increased of the pus being forced toward the cranial cavity. The safer cases are those in which, the cells being superficially placed, the pus has ruptured externally, producing a swelling in the subcutaneous tissues.

Fever.—The temperature should be frequently taken in cases of acute otitis media. We expect a moderate rise when the mastoid becomes involved, but in the chronic cases there may be little or none. An elevation to 104° F. or more should at once excite suspicion of a possible intracranial complication. The type of fever differs according to the character of the cerebral disease. In brain abscess it is constantly low; in meningitis a high temperature prevails, while in septic thrombosis a characteristic remittence is observed.

In the last-mentioned disease this remittent type of fever is a very important danger signal, for at times, especially in children, it may be actually the only symptom present.

As a rule severe rigors and chills will be associated. After a chill the temperature suddenly rises to 104° F. or more when it just as suddenly drops to normal or below. Again in a few hours, there may be another chill and the temperature behaves as before.

The Pulse.—The pulse in brain abscess is slow; in meningitis it is rapid, in sinus thrombosis it is accelerated, small, and very weak.

Otorrhea.—As stated above, the continuance of pain after discharge has set in is a bad sign; we may also say that sudden cessation of the discharge with continuance or increase of pain is a danger signal of the highest importance. It points to a blockage of secretions and imprisonment of the pus in the mastoid cells, or even perhaps that the pus has found an outlet upon the surface of the brain.

A very abundant discharge—more than one would expect ordinarily from the cavity of the ear—suggests that the mastoid cells are taking part in the suppuration. A sudden flow of pus from an ear that has been discharging normally is significant and leads us to suspect that an epidural abscess has broken through the roof of the tympanum.

It must not be forgotten that intracranial complications may occur, even when, from the scantiness of the discharge, we would say that there was very little otitis. This seems to be peculiarly the case with meningitis. Sometimes no history at all of discharge is obtainable, which is true of a case which I had an opportunity to observe recently.

Deafness.—The hearing is compromised in all cases; a very high degree of deafness should be regarded as an unfavorable sign. Complete deafness indicates an involvement of the labyrinth which is a grave complication, rendering meningitis imminent.

Vomiting.—The occurrence of vomiting in association with febrile symptoms due to a middle-ear inflammation, is a symptom of the most serious significance. If it be of the so-called projectile type, and if we can eliminate other causes, as some digestive disturbance, we may regard it as surely an indication of a cerebral complication.

Vertigo.—Severe vertigo and a general unsteadiness of gait should excite suspicion. This symptom may occur from trouble in the labyrinth; but it also is an important symptom of a cerebellar lesion.

Mental Symptoms.—Of course the development of any mental symptoms will be interpreted as pointing to something wrong in the cranial cavity. It is important, therefore, to be on the lookout for any, as even an apparently unimportant change in disposition, an unnatural moroseness, restlessness, flightiness, somnolence, or slowness of cerebration under the circumstances is extremely significant. When a true delirium, coma, or aphasia develops we can of course have no doubt of what is signified.

Among other symptoms we should mention nystagmus, ptosis, and paralysis of the eye muscle, dysphagia, yawning, and inequality of the pupils. Torticollis points of course to meningitis; but sometimes the patient complains merely of a stiffness of the neck.

A thick indurated cord running along the front of the sternocleidomastoid muscle is a sign of thrombosis of the jugular vein. Whenever there is marked edema extending beyond the region of the mastoid and into the neck, especially if involving the eyelids, we have strong additional evidence of thrombosis of the cerebral sinuses.

Disturbances of speech or vision may also occur, and when they do they may give valuable clues to the seat of the trouble. It is of course well understood that none of these symptoms, occurring separately will be sufficient as a basis for a diagnosis. It is only when they are considered with other symptoms that conclusions can be safely drawn.

Intense cephalalgia may come from a number of causes, and might have no connection with a coexisting suppuration of the ear. But if the headache has the characteristics we noted above, and if at the same time the patient has a persistent high temperature, vomiting, and delirium, we would certainly feel justified in attributing the headache to an intracranial disturbance and most likely a meningitis; if we observe in addition an inequality of the pupils, if the patient exhibits an intolerance of light, and has torticollis, and if we find Kernig's symptom present, the diagnosis may be made with reasonable positiveness; if, finally, we tap the spine and find pus, the diagnosis is confirmed beyond doubt.

Again chills with remittent fever, in connection with a suppurating ear, strongly suggest thrombosis. But it may be due of course to a mere coincidental association of malarial fever; if we have at the same time, however, typical projectile vomiting, vertigo, and cephalalgia, the probabilities are all in favor of an intracranial cause of the symptoms rather than of their being due to a simple malaria.

In closing let me warn against a too hasty diagnosis of intracranial complications in young children, upon the occurrence of symptoms which in adults would be conclusive. It is well known that in young children a simple suppuration of the ear may be accompanied by symptoms of meningeal irritation of a very alarming character, without the intervention of an actual brain lesion.

But even here we must be on our guard, for the reverse may also happen; it is especially in children that sinus thrombosis may occur, running an almost symptomless course, and with no characteristic indication whatever of any intracranial trouble.

The Rochambeau, 815 Connecticut Avenue.

PARAMYOCLONUS MULTIPLEX (FRIEDREICH).*

REPORT OF A CASE, WITH BRIEF DESCRIPTION FROM OPPENHEIM.

By E. M. VAN BUSKIRK, M.D.,

AND

ALFRED KANE, M.D.,

FORT WAYNE, IND.

This disease was first described by Friedreich in 1881. The observations made later by others are only partly similar to the original ones of Friedreich. The disease is characterized by clonic muscular contractions, occurring mostly in the body and limbs, rarely in the facial muscles. The contractions are short, sharp, lightning-like, unsystematized; they may occur symmetrically on both sides of the body, do not occur synchronously or rythmically, may be disseminated or localized, and may involve a single muscle or a whole muscle group. Active movements are not, as a rule, hindered, and have a restful, spasm-stilling influence; the opposite is true of the emotions. The twitchings are lessened if the attention is diverted, and disappear completely during sleep. The tendon phenomena are greatly increased. The motor phenomena of irritability are generally the only symptoms noticed. All other functions are normal, even the mechanical and electrical excitability of the muscles. (Oppenheim: Diseases of the Nervous System [Mayer], 1904.)

*Case presented before the Fort Wayne Medical Society, October 6, 1908; paper read before the Twelfth Councilor District Medical Society, October 27, 1908.

This is a rare disease. Gowers collected fifty-two cases in 1895, of which only thirteen were considered true cases. (Langdon: Reference Handbook of the Medical Sciences, 1903.) Mayer, in Oppenheim's Diseases of the Nervous System, 1904, stated that nineteen cases had been described in the American literature, but none had ever been reported from the British Isles.

Case.—Patient, Miss B., age 23, American born. First seen by me at her home February 11, 1908, in the absence of her attending physician. Patient in bed, having very rapid clonic spasms of the muscles of the body, arms, and thighs. The contractions numbered about 100 a minute, involved principally whole groups of muscles of the shoulder and pelvic girdles, and any single contraction could easily be imitated. This seizure had lasted about two hours and almost subsided when I tried to obtain the ankle clonus reflex. Getting her attention in any other way would lessen the severity of the attack. The muscles of the face, hands, and legs, were not involved, but the head, arms, and legs were thrown about in bed owing to the violent body movements. The knee jerk and other body reflexes were increased, but the corneal and pupillary reflexes were normal. The patient was conscious at my visit, and gave a good history of her case.

Previous History.—Had the usual diseases of childhood, otherwise, with exception of having a tapeworm removed when about eight years of age, her history was negative, until the fall of 1906, when she had typhoid fever lasting about eight weeks, which ended with an uneventful recovery. Six months after having had typhoid fever she began to have these attacks, lasting from a few minutes up to an hour or more, the attacks varying in number from ten or twelve a day to one in a week or so. On having the first attack she was awakened in the night with these violent convulsive seizures, but has not since had such an attack during sleep.

These spasms come on without warning very often, but have been preceded by mental excitement. Sometimes she has a few quick, sharp contractions of one or more of the affected muscles before the seizure begins.

Her first series of attacks were quite frequent and severe, compelling her to remain in bed for about two weeks. They gradually became less in number and milder, and she was comparatively free of them in about two months. They returned again, with the usual severity, in September of 1907, subsiding in about six weeks. She had a number of attacks in February and March of the present year, after which she was not bothered much until July, when she had a number of spasms, which have almost ceased since September. During the intervals between the times when she has so many severe attacks, she is not entirely free, but has an occasional mild seizure.

Family History.—Father died from typhoid fever; other history negative. Mother at one time had an attack of nervous prostration, and says she is somewhat nervous at the present time. The patient was the third child of a family of four children. An older brother is living, in good health, while two sisters died in infancy, causes of their deaths unknown.

Personal History.—Commenced menstruating at fourteen years; has a scanty discharge every twenty-eight days, lasting about two days. Never had any skin disease with the exception of slight interstitial eczema behind the ears. Appetite fair. Sleep is

good when the patient is well. Bowels were constipated, but normal since taking thyroid extract.

Examinations made with assistance of Dr. A. L. Kane.—Patient, five feet tall, weighing 97 pounds. Temperature, 98.4°; pulse, 100; respiration, 18; blood-pressure, 110 and 80; hemaglobin, 60 per cent; reds, 4,000,000; whites, 14,000; polymorphonuclear, 59 per cent; large lymphocytes, 9 per cent; transition, 2 per cent; small lymphocytes, 29 per cent., end eosinopiles, 1 per cent. Skin and deep tendon reflexes are plus. Reaction of muscles to electrical formula normal. No areas of anesthesia or hyperesthesia; pain and temperature senses normal.

Examination of Eye by Dr. Bulson.—Pupillary reflexes normal, no inversion of the color fields except that there was a contraction of the white field in the left eye, and the green came very close to the red. No importance could be attached to this in the absence of other stigmata of hysteria.

Urinary Examination.—S. G. 1015, slightly acid, no sugar, no albumin. Microscopic examination negative.

Physical examination of the chest and abdomen negative; on inspection fascicular tremors of the affected muscles are noticed at times. Once the patient had a few clonic spasms of the body muscles after tapping the ligamentum patellæ. While electrical tests of the muscles were being made she thought an attack was coming on, but it did not.

She has been under my care since the first of September, 1908. As to treatment she has had thyroid extract, 5 grains, and arsenious acid, 1/100 grain, three times a day. Up to October 24, 1908, she had two mild seizures. She has gained seven pounds in weight, the bowels are regular, and there has been a general improvement in her condition.

TREATMENT OF AMŒBIC INFECTION.

By M. B. SAUNDERS, M.D.,

WACO, TEXAS.

The object of this communication is to bring to the notice of those who have cases of amœbic dysentery to treat a drug, which in the hands of some is considered very valuable indeed, while others have derived very little, if any, good from its use. I shall try to give a satisfactory reason for this failure, and show why it should be used in all cases, at least in conjunction with other treatment.

The drug is *Chaparro amargoso; Castela nicholsoni*, Hook. Synonyms: Amargoso, Chaparro bush, Goat bush. Part employed: Bark of stem. Habitat: Texas and Northern Mexico.

The U. S. Dispensatory (19th Ed.) has the following: "*Castela;* Castela Nicholsoni, Hook. This plant is reported to have antiseptic properties, probably due to a resinous principle discovered by J. L. Putegnat, and named by him Amargosin."

As is well known, amœbic infections of the intestines are very resistant to treatment and prone to relapses after either long or short intervals of time. The cause of this, I think all will admit, is our inability to get our medicinal agent in contact with all the amœbæ. By irrigations we are powerless to kill any amœbæ lying deep in the submucous coat. "We also have to take into consideration that many amœbæ are so imbedded in mucus, even when lying superficially in the intestine, that the solutions will not affect them." (Craig, in "International Clinics," 1905.) Also that amœbæ are found at times in other localities of the body; the well known tropical abscess of the liver is by far the most common secondary focus, but they have also been found in the abdomen, lung, pleural and pericardial cavities, etc.

In order to reach these deeply seated amœbæ the most logical method is systemic treatment, and in the few cases that have come my way, some twenty in number, I have gotten good results from the administration of Chaparro Amargoso. My favorite was the administration of the fluid extract, because of its convenience, in dram doses every three or four hours. Yet I have had cases that did not yield to this, but responded to infusion of the bark and stems. This is the way the natives use it. Some also include the bark of the root; in other words, making an infusion of the whole plant. This is a bitter mixture, but it is as good medicinally as it is bad in taste for amœbic troubles. The infusion is drunk freely three times a day before meals, the treatment usually lasting from three to twelve months. This not only checks the dysentery, but will cause small hepatic abscesses to become sterile, and under continued use I should look for their disappearance. Large abscesses are, of course, to be treated surgically.

Dr. Edward Randall, Professor of Therapeutics in the University of Texas, in answer to a query, said: ". . . . It is by no means a specific. I still not infrequently give it in dram doses every three or four hours, and sometimes get very excellent results."

The reason why we do not always get good results is to my mind well given by Dr. Allen J. Smith, Professor of Pathology at the University of Pennsylvania, formerly of the University of Texas, in answer to a similar letter of inquiry: "I have seen numerous cases rapidly improve and become well and remain well after use of the drug—best, apparently, when given in infusions of the plant. But I have also seen cases or been told of cases where its administration was of no avail, and not even productive of temporary benefit. I have not had any such in my own experience, but good men have told me of the failure, and as you know my personal eperience in the treatment of such cases has necessarily been a limited one. I think the explanation of the failure in such instances lies in one of two lines—either (and this I have had reason to suspect) the medicine was a poor preparation or was given improperly, and that in some cases the amœbæ were of little importance in the dysentery, the disease being more likely a bacillary dysentery, with the amœbæ either accidentally associated, or if of any pathogenic significance, only of minor importance. Those cases which it does suit, seem to yield as fully and readily as does malaria to quinine. I personally would employ it, in the infusion preferably, in all cases of dysentery when the amœbæ are found. If I did not quickly see a good result I would conclude that the case is not a typical amebic form, and would at once employ other measures."

The resinous principle discovered by J. L. Putegnat, of Brownsville, Texas, and named by him Amargosin, has not been fully investigated; and our ability to go into the open market and get the drug of known therapeutic activity has been unsatisfactory with me.

I hope this brief paper may stimulate those who have to deal with this important and dangerous disease to take the matter up with some responsible pharmaceutical house to furnish them a preparation of the drug which is not inert, but pharmacologically active and up to the standard, so that they may thoroughly test its virtues on this one of the most dreaded scourges of some tropical countries.

Medical Record.

New York, February 20, 1909.

PSYCHOTHERAPEUTICS AND RELIGION.

The wonderful growth of Eddyism has been viewed differently by men of the two professions into whose practice it cuts equally. The medical man is aghast at the absurdity of its teachings in regard to physical science and at the fact that so many people enjoying freedom outside of the State hospitals can be found to accept them as true or even as reasonable; he recognizes the great therapeutic power of suggestion through which its healers effect their cures, but reprobates the fatal conceit of these healers in attempting to influence in the same way a dangerous organic disease such as diphtheria. Some clergymen, on the other hand, while condemning the heresy of the new cult, not unnaturally attribute its rapid growth to its therapeutic pretensions and successes, and so there has arisen a new school among churchmen proclaiming that the church, if it would not fall, must minister to the bodies as well as the souls of men, that while the gates of hell cannot prevail against it the ways of Eddy may well do so. Hence the appearance of the Emmanuel movement so called. How far the latter is an improvement on Christian Science and how far its existence is justified by the needs of man are discussed by Dr. Henry Rutgers Marshall in an article with the above title in the *Hibbert Journal* for January. If a little error is better than a great deal, then Worcesterism is a distinct improvement over Eddyism, for the latter embraces in its therapeutic realm every ill to which flesh is heir, while the former treats only "functional" disorders. The *modus operandi* is the same in both, but the practitioners of the newer school are more intelligent or more honest and admit frankly, indeed insist, that their weapon is simply and wholly suggestion. In so far they are in accord with physicians who, consciously and unconsciously, daily employ this powerful remedy. The Emmanuel worker differs from the physician only in the kind of suggestion which he uses; he resorts largely to prayer, which is no doubt a very powerful and to many minds most palatable form—a sort of elegant proprietary suggestion, much more pleasant and, through the mystery attached to its secret composition, at times a more effective form than the somewhat crude extemporaneous suggestion of the ordinary physician.

Dr. Marshall explains away the so-called power of the mind over the body by the hypothesis of "parallelism" held by many, if not most, of the psychologists of the present day. It is assumed that, whenever we experience any powerful mental sensation, a clear thought or emotion, or exert a determined choice, there occurs at the same time a movement of special activity in some part of the physical nervous system; that is, that with every change in the psychic system (consciousness) there is a coincident change in the activities within the nervous system. "We note in a patient a certain morbid state of mind A, which under our hypothesis is necessarily accompanied by a morbid nerve condition α. When we make a suggestion to the patient the state of mind A is replaced by the state of mind B, and coincidently of necessity the nerve condition α gives place to a certain new nerve condition β, a fact which is usually overlooked. This new nerve condition β may be one that tends to yield a less morbid nerve condition than α, and may thus bring into existence a normal nerve condition γ, which is evidenced by the appearance of a corresponding happier mental condition C." The same thing occurs, of course, when the patient makes the suggestion to himself. Religion, therefore, according to Dr. Marshall, has no essential connection with psychotherapy. The only reason for combining the two is that, as one can hardly doubt, many persons now cured more or less permanently by the Emmanuel workers or the Christian Science healers would not be relieved were they persuaded that there was nothing mysterious or miraculous in the mode of treatment employed.

Are then those who accept this explanation of psychotherapy justified in countenancing what they regard as deception for the sake of relieving suffering? Dr. Marshall says no. "Those who believe that relief from pain is of the highest significance in this world would urge us to avoid the awakening of the intellect if this awakening means the continuance of human suffering. There are those, however, with whom the author of this paper allies himself, who feel that other ends are more important than the hedonistic, and that the greatest nobility of character cannot be gained until men are willing calmly to face the facts of life as they comprehend them; that in the long run it will be better for the race to risk the continuance of some suffering among weaklings whom the arts of magic can alone relieve, rather than to curtail the development of clear thinking among the common people."

WHAT IS TYPHOID FEVER?

This is a much more difficult question to answer than it would have seemed to be ten years ago. Then the presence of *Bacillus typhosus* established the diagnosis. But with the development of the Widal test it began to be evident that the classical symptoms and clinical course of typhoid fever might be present without the specific bacillus. Then the discovery was made of paratyphoid fever with symptoms similar to those of typhoid, but as a rule milder, and with its own specific bacillus, or rather two bacilli. Then other cases were found in which the same clinical appearances were present

but without either the typhoid or the paratyphoid bacillus. Finally, as Warren Coleman wrote in *American Medicine* some six or seven years ago, it became necessary to abandon the idea of the specificity of typhoid fever in order to avoid hopeless confusion, and "to broaden the scope of the etiology of typhoid fever to include . . . . *Bacillus fecalis alkaligenus (?), Bacillus typhosus, Bacillus paratyphosus,* and certain members of the paracolon group (betaparatyphoids)." This list has since been gradually lengthened, and now contains *B. enteritidis, B. psittacosis,* and *B. coli* in addition to those before mentioned. The part taken by the last-named organism in the production of clinical typhoid fever is discussed by Warren Coleman and T. W. Hastings in the *American Journal of the Medical Sciences* for February, and the fact of such production is shown beyond question. A number of cases are reported and the literature of the agglutination reactions for *B. coli* is reviewed at some length.

The fact of this nonspecificity of clinical typhoid fever being established, the question arises: what is typhoid fever; is it a disease with definite clinical symptoms and course, but with a variety of bacterial causes, or is it the only one of such clinically identical infections associated with the presence of the typhoid bacillus? Coleman and Hastings favor the clinical classification, and rightly, for bacteriological classification would necessitate the employment of a separate term for each form of infection. It would be a simple matter to qualify the term bacteriologically whenever it might seem to be advisable, as we do now in the case of pneumonia. Moreover a bacteriological classification would necessitate the grouping of clinically distinct diseases, for not all infections, with the colon bacillus for example, pursue a typhoid-like course.

It will be interesting, in the light of the new views regarding the specificity of typhoid fever, to observe the effect of preventive inoculations. Will they protect only against the typhoid of the Eberth bacillus, or will they fortify against the attacks of all the bacilli of that group—the *Typhaceæ,* as Loeffler suggests that they be called? A group agglutination sometimes occurs, so that the Widal test may be positive even when *B. typhosus* is not present, but this is not invariable, and it would not be safe to argue from this as to the efficacy of antityphoid vaccination. At all events the inoculations seem to protect against what appears to be the most serious of the clinical typhoid infections.

THE RIGHTS AND DUTIES OF A TRAINED NURSE.

The feeling is universal that the moral plane and professional ideals of the trained nurse are similar to those of the physician. Doubts of the correctness of this conception, however, might be occasioned not infrequently by the experience of physicians in this city at the present day when they have occasion to seek the services of trained nurses from some of the more important registries. The physician who asks for a nurse is frequently obliged to undergo a crossexamination as to the circumstances of his case before one can be secured. The majority of nurses in the registries connected with the large training schools of this city are on record as being unwilling to accept employment in cases which do not come up to their requirements. For instance, Miss A. is registered against night work; Miss B. against contagious cases; Miss X. against patients where there are children in the family; Miss Y. against nervous diseases. An appeal came recently from a physician in a neighboring town to send a trained nurse to care for his very sick child. The request was refused at two of the registries in this city connected with the large training schools, although at one of them at least there was a long list of unemployed nurses. The reason given for refusal was that the nurses did not wish to leave the city just before Christmas.

It may be said with some justice that the law of supply and demand should apply in the case of the services of trained nurses as well as of those of clerks or laborers or of the sale of commodities in general, but among the nursing profession itself there will be a majority to repudiate indignantly the applicability of such a law to their case. They assert and believe that the trained nurse's duty is first of all to be of service in the world of suffering, and secondly to consult her own convenience. At a recent meeting of trained nurses, graduates and students, speeches by training school superintendents and other women high in the councils of the profession showed the prevailing sentiment to be that the time was past for them to solicit favors from the medical profession. The two professions should meet on an equal basis and confer for their mutual benefit. On the same occasion, however, one woman, a teacher of nurses and of nursing, appealed with single-hearted earnestness to student nurses to keep in mind this thought: not how much they could get out of the profession of nursing the sick, but rather how much they could put into it. To give the best of themselves, with the simple old-fashioned idea of making the world a little better. What a contrast!

At a large hostelry in this city used by graduate nurses exclusively there has been a dearth of work and some real privation for many months past. Yet perforce must the physician often go to graduates of rural training schools, undergraduates, and untrained nurses, while scores of our most highly trained nurses remain idle. It would seem to the physician that they refuse his cases at times on unwarranted or trifling grounds. It might be well would physicians make their feeling upon this matter known to nurses generally with the possible result that the best equipped women among the latter may not be led away from the high ideals of their profession even at the risk of occasional personal inconvenience.

A GOVERNMENTAL STUDY OF CHILDREN.

In a special message to Congress on Monday of this week, President Roosevelt urged the enactment of legislation to bring the laws and practices in re-

gard to the case of dependent children in all federal territory into harmony, and especially recommended the establishment of a federal Children's Bureau. A bill to that effect was introduced in the House by Mr. Herbert Parsons on December 15. This bill provides for the establishment in the Department of the Interior of a bureau to be known as the Children's Bureau. The bureau is to be under the direction of a chief, to be appointed by the President, by and with the advice and consent of the Senate. The bureau is to investigate and report upon all matters pertaining to the welfare of children and child life, and especially to investigate the questions of infant mortality, the birth rate, physical degeneracy, orphanage, juvenile delinquency, and juvenile courts, desertion and illegitimacy, dangerous occupations, accidents and diseases of children of the working classes, employment, legislation affecting children in the several States and Territories, and such other facts as have a bearing upon the health, efficiency, character, and training of children. The bill further provides for an assistant chief, to be appointed by the Secretary of the Interior, and also for a complete staff of clerks, copyists, typewriters, etc., at definite salaries. It is also ordered that the chief shall, from time to time, publish the results of the investigations conducted by the bureau.

This bill seems to be in accord with the views of the President who says, with perhaps a little overemphasis: "It is not only discreditable to us as a people that there is now no recognized and authoritative source of information upon these subjects relating to child life, but in the absence of such information as should be supplied by the federal government many abuses have gone unchecked; for public sentiment, with its great corrective power, can only be aroused by full knowledge of the facts."

If the bill is to be passed, we think it could profitably be amended in a few particulars. For instance, it might be well to provide that the chief should be a man with some training and experience in child-study and that among his assistants should be included an anthropologist, a criminologist, a psychologist, and a sociologist. The appointees in new departments, and long established departments as well, are too often men of no special training to fit them for the position, and so, even if they are men of good intentions and not mere political hacks, much valuable time is lost while they are learning the duties of their new positions and familiarizing themselves with the details of the work. This is especially important in the case of a new bureau in which there is not already a staff competent to carry on the routine work while the chief is learning what to do and how to go about it. It is much better to start right than to depend upon future legislation to remedy defects which experience in the conduct of the bureau will show to exist; and it is especially important to ensure the appointment of a thoroughly competent chief, for upon his efficiency, technical knowledge, and executive ability will depend in great measure, if not entirely, the success or failure of the new undertaking.

Autoserotherapy (?) in Serofibrinous Pleurisy.

Two Italian physicians, Gilbert and Fede, have lately reported an original method of treating pleurisy with effusion, consisting in the subcutaneous injection of a small amount of the fluid obtained from the pleural cavity by means of a small aspirating syringe. This procedure usually led to the resorption of the fluid in the pleural cavity, though the aspiration and the subcutaneous injection had to be repeated several times in some of the cases. In the *Berliner klinische Wochenschrift* for January 18, 1909, Schnutgen reports his experience with this method. He treated in this fashion fifteen consecutive cases of "wet pleurisy" aspirating one or two centimeters of the fluid and injecting it into the subcutaneous tissue by simply withdrawing the needle from the pleural cavity and directing it under the skin, which method saved the necessity of making more than one puncture in the skin. In a few cases a single injection of the fluid was sufficient to start the resorption of the exudate, in others such injection had to be repeated several times. The effect of the injection upon the rapidity of absorption could be well estimated by the increase in the daily amount of urine excreted by the patients, which took place shortly after the injections. Schnutgen tried a similar procedure in other conditions characterized by the appearance of fluid in the serous cavities, namely in cases of ascites, of hydrothorax with ascites, and of hemorrhagic and purulent pleuritis, but met with no results comparable to those obtained in cases of pleurisy with serofibrinous effusion. The results obtained are of course very interesting though more work is required before the disappearance of the effusion may be surely attributed to the simple procedure recommended by the Italian physicians. Moreover, the procedure can have little more than an abstract interest, since the operation for removal of a few centimeters of the fluid is no less serious than that for the removal of the greater part of the effusion. One may also legitimately question the part taken by the injected fluid. It is well known that aspiration of a portion of a pleural effusion may inaugurate a process of absorption, and it is possible that the removal of even the small amount taken away by Schnutgen might so alter the intrapleural tension as to start the absorption process, wholly apart from any action of the fluid injected into the tissues of the chest wall.

Legislation for the Prevention of Blindness.

That from twenty-five to forty per cent. of the blindness in Illinois could have been prevented by simple and safe remedies applied at birth is one of the potent arguments to be used to secure legislative action. The Illinois Commission to inquire into the condition of the blind is preparing to go before the Legislature with a request for cooperation, proper authority, and legal means to save the eyes of babies. At the same time, the Commission will ask the Assembly for new laws providing more adequate protection, education, and care for the blind who already are wards of the State. The State Commission has presented an exhaustive report, embodying the various bills, first to prevent blindness in the new-born, thereby stopping the rapid increase in the number of blind; the enlargement of the State School at Jacksonville; the rejuvena-

tion of the Illinois Industrial Home for the Blind at Chicago; to care for the aged blind; to create a State Commission for the Blind; and to appropriate one thousand dollars for a State Census of the Blind. Dr. William H. Wilder has written that portion of the report relating to the prevention of blindness. According to the census of 1900, he finds there were in Illinois 3,767 blind persons. Comparing this number with those of former decades, he says that in 1870 there were 41 blind to every one hundred thousand of population; in 1880 the number was 85 to every one hundred thousand; in 1890, 74 to every one hundred thousand; and in 1900, it was 78. Thirty-five per cent. of the blind reported in 1900 were blind before the age of twenty. In considering the prevention of blindness, Dr. Wilder classifies cases under three heads: First, those that are absolutely incurable or non-preventable, such as atrophy or wasting of the optic nerve, tumors of the eye, congenital blindness. Second, those which might possibly be prevented, such as injuries, inflammation of the deeper structures. Third, those caused by infectious inflammations of the conjunctiva, all of which could be prevented by proper treatment. What is needed is the enforcement of a law requiring better training of midwives and their registration. They should be compelled to report every birth and every case of this disease as soon as it develops, and also be trained in the use of prophylactic measures against ophthalmia neonatorum.

News of the Week.

Shorter Medical Course.—Representatives of twenty-four colleges of New York State conferred with Dr. Draper, State Commissioner of Education, on February 9, regarding a change from the present rule of Board of Regents requiring a seven year course for the combined A.B. and M.D. degrees, or the B.S. and M.D. degrees. A number of colleges have petitioned for a reduction of the time to six years, and it is thought that the regents will act favorably upon this suggestion at a future meeting.

Spitters Arrested.—The Board of Health officials of this city, finding that the public was utterly indifferent to, and the police lax in enforcing, the ordinance against spitting in public places, sent out a general order to the policemen connected with the Department last week, with the result that two hundred men were arrested on the elevated and subway stations in a single day. The majority were taken to police courts where they were fined sums varying from fifty cents to three dollars.

New York City Deaths.—During the week ending February 6, there were thirty-nine deaths less than for the corresponding week of last year. Of the total ninety-five were due to heart disease, eighty to pulmonary tuberculosis, thirty-eight to violence, and four to typhoid fever.

Death Rate in Chicago.—For the week ending February 6 the death rate in Chicago was 13.88, which is a considerable reduction from that of last year. The total number of deaths was 592, as against 747 for the same week last year.

Scarlet Fever Epidemic.—During the last few weeks there has been an epidemic of scarlet fever on the receiving ship *Hancock* at the Brooklyn Navy Yard. Eleven cases have developed, but it is thought that the prompt measures taken will prevent further spread of the disease.

Against Marriage of the Sick.—A bill has been introduced into the Pennsylvania Legislature forbidding the marriage of persons suffering from pulmonary tuberculosis, epilepsy, insanity, imbecility, idiocy, or other hereditary disease.

Ventilation of Theaters.—Eighteen five-cent theaters in Chicago have been ordered to install adequate systems of ventilation. Prosecutions will be started against those failing to comply. Investigations are also being made as to the ventilation of suburban trains entering Chicago, and data for suits are being collected. The Department of Health has already begun suits against some of the steam and elevated railroads, and intends to push the matter vigorously until some adequate means of ventilation is provided.

New Ambulance Service.—The National Volunteer Emergency Service, of which Major-Gen. James E. Pilcher is director, has decided to undertake work in the field left open by the withdrawal of the Roosevelt Hospital ambulances on March 1. The Emergency Service proposes to open ten first-aid stations in drug stores on the West Side between Twenty-fifth and 125th streets. Each station will be equipped with an army litter, an emergency bag, blankets, pillows, a hot water bag, a poncho (in case of rain) and a lantern. Attached to each station, within easy call, will be surgeons, two druggists, two trained nurses, and twelve citizens, or laymen. When patients treated by this service require hospital care they will usually be taken to the Red Cross Hospital, unless they prefer another. The Emergency Service already has four such stations in operation in Manhattan, one in Brooklyn, one in Elmhurst, and one in Hoboken.

Presbyterian Hospital to Move.—The managers of the Presbyterian Hospital have taken title to the block bounded by Sixty-seventh and Sixty-eighth streets, Avenue A and the East River, and it is proposed to move the hospital to this location where it will be closer to the centers of population. This site was the selection of the late Dr. Andrew J. McCosh. Work on the new buildings will probably begin about May, 1910, and the hospital when completed will occupy a bluff fifty feet above the river. The sale of the old property on Madison avenue is expected to make a considerable addition to the building fund, which already includes a gift of $1,000,000, made last October by Mr. John S. Kennedy. The new site is said to have cost about $500,000. The Presbyterian Hospital was opened on May 10, 1872. During the year ending September 30, 1908, 43,220 persons were treated at the hospital, and of the 3,536 patients who occupied beds 65 per cent. were free patients. The ambulance district covered by the hospital extends from Fifty-ninth to Ninety-sixth street, east of Central Park to the river. During the last year the ambulances responded to 3,479 calls.

Chicago-Winfield Tuberculosis Sanatorium.—This new sanatorium was opened February 7. The ground and buildings were presented by Charles A. Stonehill to the Baron Hirsch Woman's Club, the Jewish Consumptive Relief Society, and Willing Workers. Several cottages, each accommodating ten patients, are to be built soon. The endowment amounts to about $12,000 a year at the present time. The chief of the staff is Dr. Theodore E. Sachs.

Theater Benefit to Hospital.—As a result of a theater benefit given recently, the National Emergency Hospital received $250.

Gifts to Charities.—The Homeopathic Hospital and Maternity of Yonkers, N. Y., receives $20,000 by the will of the late Mrs. E. S. Cochran of that city.

By the will of the late Mary Lewis of Philadelphia a bequest of $10,000 is made to the Episcopal Hospital and bequests of $5,000 each to the Polyclinic Hospital, the Hospital of the Woman's Medical College, and of $2,000 each to the Seaside Home for Invalid Women, the Home for Consumptives, the West Philadelphia Hospital for Women, and the Kensington Hospital for Women.

Medical Inspection in Public Schools.—In his annual report to the Board of Education, City Superintendent Maxwell urges the establishment of a department of hygiene, which would take over from the Department of Health the examination of school children except in cases of contagious diseases. Such a department could advise parents in regard to the health of children, and might even invoke the law upon the neglectful. The report states that medical examination thus far has shown a large number of children suffering from malnutrition as a result of bad or insufficient food, and urges the establishment in the schools of facilities whereby pupils may obtain wholesome food at cost price.

School Inspection in Chicago.—Medical Inspectors of the Schools examined 11,372 school children during the week ended February 6, and excluded 446 from attendance on account of contagious diseases. The chief causes of exclusion were as follows: Diphtheria 8, contacts 8; scarlet fever 17, contacts 8; measles 8, contacts 13; whooping cough 2, contacts 1; chickenpox 45, contacts 33; mumps 42, contacts 11; tuberculosis 1; tonsillitis, 77; pediculosis, 47; scabies, 31; impetigo contagiosa, 41; ringworm, 29; conjunctivitis, 21

American School Hygiene Association.—The third meeting of this association is to be held in Chicago February 22-25. On February 23 the president, Dr. Henry P. Wolcott, chairman of the Massachusetts State Board of Health, will deliver his annual address.

Medical Society of the County of Kings.—At the annual meeting of this society held June 21, 1909, the following officers were elected: *President,* Dr. Joshua M. Van Cott; *Vice-President,* Dr. John C. MacEvitt; *Secretary,* Dr. Henry G. Webster; *Associate Secretary,* Dr. William A. Jewett; *Treasurer,* Dr. John R. Stivers; *Associate Treasurer,* Dr. Henry M. Mills; *Directing Librarian,* Dr. James P. Warbasse; *Censors,* Drs. Ralph H. Pomeroy, Russell S. Fowler, Albert M. Juddy, J. Richard Nevin, and Warren S. Simmons; *Trustee,* Dr. Onslow A. Gordon.

Alumni of the College of Physicians and Surgeons.—To celebrate the fiftieth anniversary of the founding of their association, the Alumni of the College of Physicians and Surgeons, New York, will meet at a dinner to be given at Sherry's on March 2, at seven o'clock. Prof. Samuel W. Lambert, Dean of the College and President of the Association, will preside, and among the speakers will be Dr. Nicholas Murray Butler, President of Columbia University; Mr. Seth Low, Trustee and former President of the University; Dr. H. A. Christian, Dean of the Harvard Medical School; the Rev. Dr. Richards of the Brick Presbyterian Church, New York, and Prof. John G. Curtis, of the College of Physicians and Surgeons. An attempt will be made to seat College and Hospital graduates according to the date of graduation. Tickets for the dinner may be obtained on or before February 26 by addressing Mr. E. T. Boag, College of Physicians and Surgeons, 437 West 59th Street, New York.

The Physicians' Mutual Aid Association of this city has been declared by the attorney-general of the State to be guilty of violation of the insurance law in having made a personal loan to its treasurer.

Centenarian Dies.—Julian Terrian of Belleville, Ontario, said to be the oldest man in the Dominion of Canada, died on February 12 in his 111th year.

Obituary Notes.—Dr. Adolph von Düring of New York died on February 10 from blood poisoning following an injury to his finger in the course of an operation. Dr. von Düring, who was born in Germany in 1853, was graduated from the medical department of New York University in 1885.

Dr. John T. Fritts of Plainfield, N. J., died at his home on February 8, aged 63 years. He was graduated from Bellevue Medical College in 1866, and had practised in Plainfield since 1878, up to a few years ago. He was a member of the American Medical Association.

Dr. Charles H. Roberts of New York died on February 11, aged 88 years. Dr. Roberts was graduated from the Albany Medical College in 1846, but had practised very little, devoting most of his time to locating Western lands and speculating in real estate.

Dr. Brenno Bribach of Carondelet, Mo., died on January 29, aged 63 years. Dr. Bribach was a native of Germany, where he received his early education. Coming to this country in 1868, he entered the Missouri Medical College. He was a member of the American Medical Association and the St. Louis Medical Society.

Dr. Edward H. McCabe, at Dagsbror, Sussex County, Delaware, on February 6, at the age of 67 years. He was a graduate from the Long Island Medical College Hospital in the class of 1874.

Dr. John Campbell died at Philadelphia on February 4 at the age of 81 years. He was born at Washington, Pa., and entered Washington and Jefferson College in 1843 and was graduated in 1847. He practised medicine in Tranquility, O., until the breaking out of the Civil War, when, in association with Capt. John T. Wilson, he recruited Company E of the 70th Regiment of Ohio, and was commissioned first lieutenant, later becoming captain of Company I of the same regiment, and serving from October 1, 1861, to November 4, 1864. He abandoned the practice of medicine in 1885 to become medical referee in the Pension Bureau in Washington, D. C., under President Cleveland. In 1889 he became a district inspector of the Equitable Life Assurance Society of the United States, with offices in Philadelphia, holding this position until the time of his death.

Dr. C. P. Gerrish of South Berwick, Maine, died on February 2 of cancer of the stomach, aged 79 years. He was graduated from Bowdoin Medical College in 1853, and had practised in South Berwick for forty-one years.

Dr. Julian A. Buel of Franklin, Mich., died at his home on February 4, aged 69 years. He was a graduate of the University of Michigan, and had been in active practice for forty-three years.

Correspondence.

THE EVIL OF FOOD PRESERVATIVES.

To the Editor of the Medical Record:

Sir:—The recent convening of the American Association for the Promotion of Purity in Food Products in New York City is an epoch-making event in the history of pure food in this country. The sole aim of this association is the protection of the public by the abolition of chemical preservatives in food products. The results of the meeting were momentous and will be far-reaching in their effects. A platform was adopted declaring that chemicals are absolutely unnecessary in the preparation of any food products, that the only excuse for their use is to adulterate foods and conceal inferiority in raw products and inadequacy of the process of manufacture; that chemically prepared foods are injurious to health, and that the legitimate element of the trade does not care to bear the stigma of putting out chemically treated foods, even though some of those men entrusted with the enforcement of the law should be able so to interpret it as to allow the use of chemicals.

In addition, the following resolution was adopted and sent to President Roosevelt:

"Whereas, Opinion of leading scientists in both Europe and America is divided upon the subject of artificial preservatives in prepared foods, there being great weight of opinion on both sides of the controversy, thus leaving the question of their injuriousness or otherwise still in doubt; and,

"Whereas, As practical manufacturers, we know that artificial preservatives of any kind are unnecessary to the successful commercial preparation of good, sound, raw materials, under proper sanitary conditions, thus making it both possible and reasonable to give the consuming public rather than the reactionary manufacturing interests the benefit of that doubt; and,

"Whereas, The use of artificial preservatives makes possible and invites the employment of inferior and waste materials often unfit for human consumption, and careless methods and unsanitary conditions in food preparations; and,

"Whereas, We believe that not only will the reputation and standing of the great American food producing industry be jeopardized, but that the interest of all the people will be sacrificed by any action on the part of the Government that permits the continued use of any artificial preservatives in any food product. Now, therefore, be it

"Resolved, That we are opposed to any ruling under the National Food and Drugs Act of June, 1906, that permits the use of artificial preservatives in foods, or that in any way departs from either the letter or the spirit of that law. Be it further

"Resolved, That these resolutions be transmitted by telegraph to the President of the United States, as expressive of the sentiment of this association."

Some day the people of this country will take hold of the food interests and compel the adulterating manufacturers and the politicians to cease juggling with the health and life of the community.

It is no wonder that there is some confusion in the public mind when experts disagree as to the quantity of poison allowable to a manufacturer. "Business interests," of course, must be considered first before the health of the nation, and if it is possible for the human stomach to take in embalming chemicals and live—that is all that is demanded. Now the question of benzoate of soda will not be settled finally until it is settled by the people. As long as there are any experts who claim that preservatives in food are injurious (and there are many both in America and Europe), we should be on the safe side and abolish them, especially as there can be no argument adduced for their use when so many manufacturers of food products carry on their great factories without them.

Why, then, the public asks, all this struggle on the part of some food manufacturers for the legal privilege of using preservatives? The answer to this question is the whole point of the food fight and leaves no doubt as to the motives and principles of the men who use preservatives. Without benzoate of soda and similar chemicals their products would not keep sufficiently, for the reason that they are put up under unsanitary conditions or are inferior cannery waste which would not be marketable but for artificial preservatives. The factories where no chemical preservative is used are the safe ones to patronize, not only because the consumer should not voluntarily put poison into his system, but because the materials used, fruits, meats, poultry, and vegetables, are pure, whole, sweet, untainted, and wholesome. Those factories whose output is chemically preserved are at least open to suspicion, and it is positively known that some of them use these artificial substances to render attractive and palatable inferior raw material, often too offensive in character even to think about. Everyone versed in food matters knows that expensive factories are built for the purpose of utilizing garbage carted away by the ton from the floors of canning factories, and marked "for use when wanted." Such refuse consists of tomato skins and cores, apple parings, worm-eaten and decayed portions cut from fruit, all swept up and sold. Such filth, which in the individual house would be tossed into the swill pail, is used to make catsup, soup, apple butter, jam, and mince meat. The adulterers who place this output on the market very naturally know that, were chemical preservatives forbidden, their business could not be maintained for twenty-four hours. Manufacturers of pure food suffer in the eyes of the public because the consumer does not know in most cases how to discriminate between the innocent and the guilty, and to be on the safe side has spells of refusing to buy all canned products. Nothing is more sanitary, beautiful, clean, and wholesome, however, than the factories which are putting up pure food, guiltless of preservatives.

Although the worst evil is the spoiled materials covered up by the use of benzoate of soda, the chemicals themselves are more than doubtful. It may be possible for robust young men, pre-examined and found sound, to absorb small quantities of this for a few months and not suffer serious injury—such constitutions might throw off disease in any form—but that delicate children and old people, and those with stomach, liver, or kidney disorders, persons weak and impoverished, would be so fortunate is extremely unlikely. Even small quantities of poison continually administered to the system make for cumulative harm, and an eight-course dinner might easily contain poisons whose combination would be most harmful. Even if some chemists discredit the idea that small quantities of preservatives are vitally harmful, they scarcely could maintain that they are beneficial. Therefore, it would seem unnecessary and very unwise to introduce these deliberately into the human system.

Benzoate of soda has been compared with salt as no more poisonous, but aside from the absurdity of such a proposition, it at least cannot be tasted, and nature rebels at overdoses of salt and sugar. The referee board in its wisdom has decided that an individual may eat one-half gram per day of benzoate of soda and live; how is each individual—compelled to consume what he can get, in this hurried and complicated civilization—to ascertain when he has absorbed his one-half gram of poison?

That the first-class food manufacturers are unanimous in their theory and practice of not using preservatives, and are willing to forget that they are business competitors and join hands in the fight against adulteration, notwithstanding this finding of the referee board, is an unanswerable argument. When President Roosevelt realizes the position of these manufacturers who have proven their contention by their own experience he will doubtless realize the benefit to the American people in sustaining Dr. Wiley in his unflinching opposition to food preservatives. In its fight against adulterated food products the American Association for the Promotion of Purity in Food Products is waging a battle for eighty millions of people in this country, every one of whom is innocently exposed to the dangers that lurk in chemically treated foods.

Editor *National Food Magazine*

New York

HYDROTHERAPY.

To the Editor of the Medical Record:

Sir—It is a rather strange fact that in America the physiological methods of curing disease, and especially hydrotherapy, are hardly ever employed at all. Evidently there have been no results worth mentioning otherwise those methods would without doubt have forced their way into medical practice in this country.

But why have these results been so poor? I cannot, here, enter into all details of this matter, but would like to call attention to the fact that the technique of these

methods is wrong in many cases and that, for instance, hydrotherapy as it is practised here hardly deserves this name at all. Of course, as Winternitz remarked once, one can practise hydrotherapy with a pail of water and a rag, but fortunately the technical side of hydrotherapy is well developed and we can very easily adapt our methods to the individual circumstances. But it cannot be too often repeated that the bath attendant should only obey orders and never act upon his own ideas, no matter how experienced and thorough he might be. But although we have here very few carefully trained bath attendants, the choice of methods is usually left to them. This is a grave mistake, which bears its own punishment and which is one cause why hydrotherapy has made little headway in this country. The bath attendant is not so much interested in the welfare of the patient as the physician; he naturally seeks to spare himself trouble, and so gives the same treatment to every patient. That is why hydrotherapy in America consists chiefly in putting the patient into a hot-box for some time and in pouring more or less cold water over him afterwards.

In a recently published paper a physician recommends the treatment of the insane in the following way: The patient should be put in a hot-box for 15 minutes, then a shampoo with warm water and soap is to be given, and finally comes a shower bath at a temperature of from 102° to 105° F. The patient would really have to be quite insane to allow himself to be treated that way. But it shows that his bath attendant was formerly attendant in a Turkish bath and is trying his thus acquired knowledge on the poor patients. But this certainly cannot be called hydrotherapy. The method of treatment has, naturally, to meet the special indications and to be closely adapted to the condition of the patient, and ought therefore to be prescribed only by the physician, although of course it must be carried out by a thoroughly trained attendant.

Hydrotherapy is here almost exclusively used in treating rheumatism, acute infectious diseases, and insanity, and yet the efficacy of this method in a number of other forms of disease is acknowledged. Unfortunately the technical means employed here are inadequate. Half-baths, packs (wet and dry), dripsheets, and many other methods which are of the greatest effect are practically unknown. The systematic use of hot baths has hardly been suggested. There are some very good books which give ample and thorough instructions on the technique of hydrotherapy. Two of them are published in America: Baruch's "Hydrotherapy," and Kellog's "Rational Hydrotherapy." A careful study of such books would go far to place the practice of hydrotherapy on a higher plane than that it now occupies.

CARBOLIC ACID IN ERYSIPELAS.

To the Editor of the Medical Record:

Sir:—The article by Dr. Aspinwall Judd on the treatment of erysipelas by means of carbolic acid and alcohol, which appears in the Medical Record issue of February 13, should be read by the profession with no little interest. The method employed by him to combat the ill effects and spread of erysipelas I have used for at least twenty-five years, and, as Dr. Judd says, the only toxic manifestation due to its use in the treatment of such cases I have noticed is a dark color given the urine. This phenomena can be obviated by a sparing use of the acid in cases where large surfaces are involved.

Alcohol in moderate quantity, internally, promptly overcomes any clouding of the urine, it is given upon the hypothesis that if alcohol applied locally lessens the effect of the carbolic acid, it naturally would have the same tendency so to influence the secreting surface of the kidneys due to its coming in contact with such structures. I have not had a case in years that did not yield promptly upon the application of carbolic acid, and it is a marvelous fact that the erysipelatous patient responds so promptly to this medicament. Its use usually prevents the formation of blisters containing exuded matter. I have become so thoroughly convinced of the virtue of carbolic locally applied in cases of erysipelas that I use it right along in a routine way, of course being scrupulously careful to watch the urine. When there is an extensive area to be treated I use it very sparingly and sometimes diluted by the addition of glycerine, which, with carbolic acid, makes a good admixture.

Chicago. C. S. Eldridge, M.D.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

RADIUM INSTITUTE—RADIUM IN SURGERY—TISSUE ANTISEPTICS AND ANIMAL INFECTIONS—SALICYLATES AS RETENTIVES OF URIC ACID—OBITUARY.

London, Jan. 29, 1909.

You will be interested to learn that a Radium Institute is about to be established in London. The week has abounded in flying rumors on the subject—some of them incompatible with others. The fact that emerges is that the new scientific institution will shortly be set up. The initiative is ascribed largely to the King, who has displayed much interest in the project. So much, indeed, that some anticipated a royal charter, but there is no confirmation of any reports as to that. The financial foundation has been rendered possible by the enlightened liberality of Sir Ernest Cassel and Lord Iveagh. Sir J. Ramsay and other eminent scientific authorities have agreed to serve on the committee or council, on which also the profession will be strongly represented. Sir F. Treves will probably be the first chairman.

On Tuesday Sir Frederick went to his old school of the London Hospital and delivered a lecture on "Radium in Surgery." Of course, the students turned up in large number to hear what future was anticipated by the lecturer for the new remedy. He told them at the outset that it was necessary to exercise great caution in speaking of its potentialities. Great expectations were aroused by the introduction of *x*-rays, the Finsen light, and the high-frequency current. But they had not revolutionized surgery. The lecturer proceded to consider the diseases which radium can cure, its mode of action, and the lines on which investigation of its capabilities will probably be continued. He referred to cases he had himself seen in the Paris Institute, mentioning angiomata, which had been cured, one being a solid mass deeply seated. He thought it safe to say that there was a relation between the amount of radium used and the good it did. It would therefore not be unsound to draw the conclusion that if enough radium were available the surgeon could carry out practically what he wished so far as growths of a certain type were concerned. It would cure certain forms of eczema and rodent ulcers of many years' standing in which the tissues had become adherent to the bone and in which the Finsen light and *x*-rays had failed. Here the question arose whether these cures are permanent. No great time had elapsed since the introduction of the method, but he had seen a case in which epithelioma had been apparently cured two years previously. The cost was a serious question. If radium should become only "worth its weight in gold," that would be exceedingly cheap, but there seemed at present no prospect of such a fall in price. The lecturer next referred to the different characteristics of the α, β, and γ rays which radium gives out. If we represent the penetrating power of the α rays as 1, that of the β rays would be 100, and that of the γ rays, which would pass easily through an inch of steel, would be 10,000. The qualities of the cathode rays in a vacuum tube corresponded to the β rays; the *x*-rays and the γ rays of radium had the same characteristics, and as *x*-rays were dependent on the cathode rays so the γ and β rays were inseparable.

In the application of radium in surgery the main factor was extent of surface. A little radium spread over a wide surface was much more powerful than a great deal applied in a tube. It could be used on cloth or silk or anything that could be varnished.

The emanation which radium gives off renders anybody that is brought near it radioactive. We have no method of inducing radioactivity except from the emanation, and the lecturer considered it not improbable that the future of radium in surgery lay in the emanation. Whether it would be of use in diseases of the lungs to inhale a vapor which is capable of depositing on the air passages a radioactive substance could only be looked at as surmise.

Having referred to some of the experiments that have been made and would have to be supplemented and verified, he asserted that one of his own patients had been treated with a subcutaneous injection of a solution of the emanation over a part of the abdomen, with astonishing effects. He observed particularly that the scar left by the injection and the pigmentation of the skin were different from anything he had ever seen. Concerning future investigations, he thought it was very essential to ascertain the range of radium rays

and the effect of the emanation on bacteria and their products. Other lines of investigation were the effect of radium in large amounts, the effect of inhalation of the emanation, and the effect of injecting a solution of the emanation. Most of the radium in use was obtained from Joachimsthal, where a large spa is being erected for the public to drink radioactive water, but that, said the lecturer, proved nothing. The public would drink anything and this spa was no evidence that radioactive water had any effect.

Professor Cushny has brought before the Therapeutical Section of the Royal Medical Society the subject of tissue antiseptics with reference to animal infections. The organisms of specific fevers have acquired such a resistant power to influences injurious to their growth that the germicides tried have proved more poisonous to the host than to the parasite. But a greater measure of success has been obtained in diseases due to animal organisms, *e.g.* syphilis, malaria, sleeping sickness. This Professor Cushny attributed to the parasite being younger and so not having acquired perfect adaptation to the surroundings and consequently being less resistant to our drugs. Probably, too, it produced no toxin and so provoked no antitoxin. He had endeavored to determine the resistance of the trypanosome of sleeping sickness to arsenic, antimony, and bismuth. In all three an amount of 1 in 200,000 banished the parasite. Thus one milligramme of antimony destroyed the parasites in a 200 gram rat.

Arsenic acted more slowly. Bismuth did irreparable damage to the host. But the parasites were not all absolutely destroyed. They returned as often as they were banished at longer or shorter intervals. Finally, a race of antimony-resistant or arsenic-resistant trypanosomes was produced, which, retaining this quality, could be propagated from rat to rat. The arsenic-resistant trypanosomes, however, were still susceptible to antimony and bismuth and vice versa. Professor Cushny said possibly this might indicate a use for old-fashioned polypharmacy. If a patient were treated with all the drugs at once few parasites would survive. The trypanosome from a rat, resistant to one drug, injected into a mouse became nonresistant again to that drug. Dr. Burton Brown, who was in the chair, remarked that the way in which quinine lost its power in chronic cases of malaria might find an explanation in Professor Cushny's investigations.

A paper was then read by Dr. Alex. Haig on "Salicylates as Retentives of Uric Acid." He asserted that while large doses acted as solvents of uric acid small doses were really retentives. He contended that this was proved by the diminution in number of certain granules in the blood, accompanied by a quickening of the circulation in the capillaries. This "capillary reflex," he maintained, was an accurate measure of the amount of uric acid in the blood and he showed an instrument designed to signalize the time of this reflex, and charts he had obtained by it. These views were controverted by Drs. Luff and Cameron. The former thought it was not possible to form any estimate of the amount of uric acid in the blood from the appearances referred to. He had searched Dr. Haig's writings in vain for an account of a single estimation of the amount of acid. He went on to deny that we have any proof whatever that uric acid is a poison or that it is the cause of the numerous symptoms so constantly ascribed to it. Dr. H. C. Cameron said that apart from the question whether or not the time of the capillary reflex was influenced by the amount of uric acid in the blood there were so many varying factors which did certainly most profoundly influence it—*e.g.* temperature, posture, emotion, digestion, etc.—that he could not consider the results obtained as trustworthy.

The death occurred on Monday, 25th, suddenly of Thomas Joseph Patrick Hartigan, F.R.C.S., pathologist and surgeon in charge of the light department at the Skin Hospital and dermatologist to the Alexandra Hospital. He took the College Fellowship in 1899 and for several years devoted much attention to investigating the effects of radium. He designed a new radium applicator.

Other deaths this week are Mr. Washington L. Winterbotham, consulting medical officer of the Bridgewater Infirmary, at the age of 71.

Dr. George Ellis died in Dublin on the 27th inst. in his hundredth year. He graduated M.B., T.C.D., in 1834 and retired from practice some forty years ago.

Mr. George Eastes died suddenly on the 23d inst., aged 67. He was widely known as treasurer and president of the Metropolitan Branch of the B. M. Association and as taking a very active interest in all questions affecting the welfare of the profession. As a practitioner he devoted great attention to anesthetics, held hospital appointments for their administration for fourteen or fifteen years, and was treasurer of the Society of Anesthetists. He had served as president of the Harveian Society, when his address was on "Evolution in Treatment, 1831 to 1895." He also wrote a "Memoir of Harvey," 1871. He took M.B. Lond., 1866, F.R.C.S., 1868, having been a Guy's student, and afterward spent some time in Paris. He contributed papers to several societies of which he was a member, as well as articles to the journals. In fact, he was for several years an active member of the staff of a medical journal, in which position, as in many others, he gained the good-will of all with whom he came into contact.

Progress of Medical Science.

Boston Medical and Surgical Journal, February 4, 1909.

Osmic Acid Injections for the Relief of Trifacial Neuralgia.—H. H. German divides cases of trifacial neuralgia into three classes: (1) Neuralgia as a symptom of some general disease, as anemia, neuritis, etc.; here we generally have a definite neuritis. (2) Reflex intermittent pain due to a definite local cause, as sinus disease, carious teeth, etc., and (3) true epileptiform neuralgia, for which no definite cause can be assigned. It is to the last named class that he calls attention and summarizes the histories of eleven personal cases. He concludes that osmic acid injections will relieve trifacial neuralgia for a longer or shorter period of time. Relief from pain is not always immediate, but follows in a few days after injection. The latter may be followed by a certain amount of tissue necrosis at the needle point. The acid is little if any better than other peripheral injections. It is best used in a 2 per cent. solution in a glass syringe with a platinum needle and is to be employed only on purely sensory nerves, as its use on mixed nerves is followed by motor paralysis.

Internal Concealed Hemorrhage.—J. R. Torbert presents a general paper. He considers this form of bleeding a comparatively rare complication of pregnancy. Unless diagnosticated early it has a serious prognosis. It generally occurs in the last two months of pregnancy, although it may occur as early as the seventh month. The diagnosis is made by careful examination of both the mother and the fetus within the uterus. The author urges the importance of an examination of all pregnant women in the last months of pregnancy and the keeping of a close watch on both the maternal and fetal pulse during the progress of labor. Palpation is important in making a diagnosis, as the uterus is much increased in size and becomes of a board-like consistency. The appearance of acute anemia with manifestations of shock in a patient in the later months of pregnancy should always suggest the possibility of concealed internal hemorrhage. Early diagnosis is essential in offering a favorable prognosis to the mother; that to the child is bad.

New York Medical Journal, February 6, 1909.

Observations on Prophylactic Inoculation Against Typhoid Fever.—H. Shoemaker briefly reviews the literature of the subject and gives his experience with a small number of inoculations. He finds that the evidence of bacteriolytic and bactericidal activity higher than the normal and the presence of agglutin can be obtained from the serum of those who have been inoculated. He also believes that the results of inoculation on soldiers of the English army confirm the laboratory findings. In his own investigations the author estimates the effects produced in the blood stream by dosage upon (1) a negative and positive phase, (2) stimulus or opsonins, (3) bactericidal substances, (4) bacteriolytic substances, and (5) agglutination. With reference to the preparation of a vaccine, he says that every worker with bacterial vaccines who wishes to arrive safely and expeditiously at a vaccine which retains the greatest immunizing power should first carefully ascertain the least degree of heat which is necessary to kill the strain.

Epiploitis Following the Radical Cure of Hernia.—The patient of C. G. Cumston was a man of twenty-

four years, operated on for a right-sided inguinal hernia in March, 1906. The contents of the sac were composed entirely of omentum, a large mass of which was resected, kangaroo tendon being used for ligature. The day following the operation, which, by the way, was easy and rapidly executed, the patient complained of abdominal pain, while the abdomen was distended. On account of the distension respiration was somewhat difficult, although unaccompanied by pain. The next day the patient was extremely restless, but there was no elevation of the temperature. The bowels moved with an enema, but the distension still continued. This condition of affairs remained about the same until the eighth day following the operation, when the temperature went up 2° C., and at the same time there was an increase in the symptoms already mentioned. The abdomen became still more distended and was painful on percussion. The tongue was dry, the patient most restless. By palpation a tumefaction was detected in the right hypochondrium, extending from the costal border above, down to the iliac fossa on the same side, and was principally marked under the cicatrix of the hernia incision. The latter was in perfect condition and the stitches were removed on this day. The tumefaction was elongated in shape, with its long axis running vertically from above downward, and it appeared to be in direct contact with the abdominal wall. It felt resistant, apparently immovable, and all over its extent dullness was elicited by percussion. This mass was painful, the pain being increased by both palpation and percussion. The abdomen was still distended and constipation was extremely difficult to overcome in spite of high enemata. The temperature was 40° C., and the patient had an abdominal facies. The diagnosis of epiploitis was made. Ice bags were placed upon the abdomen and a pill containing 2 centigrammes of colloid silver was given four times daily. At the end of twelve days the temperature had reached normal and, after this time, remained so. The bowels began to work naturally, the pain diminished, and the swelling also, so that in seven weeks after the operation the patient was discharged cured.

The Physiological Action of Strong Cocaine-Adrenalin Solutions.—J. Leshure presents the following conclusions: (1) To induce a maximum degree of local anesthesia and ischemia, with a minimum of general drug absorption, it is necessary to use solutions of high density, which do not readily enter the larger blood and lymphatic streams. (2) The diluting effect of the mucous membrane secretions must be borne in mind and cotton wound applicators should be frequently changed, and freshly charged with the cocaine-adrenalin solution. (3) Before beginning to operate one should carefully test every part of the field with a probe to determine whether the anesthesia is complete. It is difficult to anesthetize when bleeding has once begun, and the patient will greatly appreciate the extra effort made to spare him needless pain.

Journal of the American Medical Association, February 6, 1909.

Suture of Heart Wounds.—G. T. Vaughan gives a historical sketch of the operative surgery of the heart and reports a case of successful suturing of a wound, one-third of an inch in length, opening into the right ventricle. Two rows of silk sutures were used and two bleeding points caught up and ligated with catgut. The pericardium was closed with a continuous catgut suture without drainage. He tabulates and analyzes the reported cases, and summarizes his conclusions substantially as follows: 1. There is no question as to the propriety of operation, since 35 per cent. of the patients recover, as compared with 15 per cent. (according to Holmes and Fisher, 1881) of recoveries after non-operative treatment of heart wounds—a gain of 20 per cent. 2. The mortality is practically the same as that of twelve years ago, when the operation was first attempted, and it behooves the surgeon to study the matter and seek for some improvement. 3. The two chief causes of death are hemorrhage and inflammation of the pleura or pericardium. Probably nearly everything possible has been done to prevent hemorrhage, but since more than half the patients who survive over twenty-four hours become infected there is room for great improvement in this respect. 4. To prevent this, besides the observance of strict asepsis, the question of opening the pleura and the drainage of the pleura and pericardium must be considered of the greatest importance. 5. As a rule, therefore, the pericardium and pleura should not be drained. The article is illustrated.

Sanitation in the Philippines.—W. E. Musgrave describes the insanitary conditions existing there before the American occupation; an insufficient and most unsatisfactory water supply derived from a dam drawing from a water shed inhabited by 20,000 people and half as many animals, a general absence of sewers, unclean market places, and a daily meeting with patients with smallpox, leprosy, etc., on the public street. Now, after ten years, a fine new sewer and water system has just been completed for the city and the enforcement of public health measures has developed a vast improvement in the personal hygiene of the natives. At present certain of the elementary essentials have become almost fashionable fads; the drinking of safe waters and the eating of safe foods has become a strict rule in all homes worthy of the name. He also credits to the influence of the board of health the modification in American costume which has contributed so largely to the success in living there. A compulsory vaccination law has made the entire civilized population protected from smallpox. Typhoid is comparatively rare, cholera epidemics have been reduced to small proportions, and parasitic diseases have been largely decreased in the capital. The segregation of lepers is almost complete. Musgrave says that ten years of American control have made of Manila one of the cleanest, healthiest, and most attractive cities under our flag.

Salt Solution Injections in Sciatica.—The use of injections of salt solutions in sciatica is discussed by D'Orsay Hecht, who reports the results of such measures in his hands. He reviews the literature of alcoholic injections in these cases and concludes that they are unsuited. The method employed is to inject into the sciatic nerve at one or more points in its course after it leaves the great sacrosciatic foramen, a considerable quantity of salt solution, and he gives the technique in detail. He has not met with any accidents in his employment of this method and the results have been surprisingly good in controlling pain. His concluding comments are as follows: "(1) The deep infiltrating perineural injections palliate the pain of sciatica. (2) The acute, subacute, and chronic types of sciatica lend themselves to this treatment, and whereas the number of injections required varies, immediate notable relief is afforded by the first injection in nearly all cases. (3) The treatment is most indicated and effective in the nonsymptomatic cases, but is also of value in the symptomatic variety. (4) Normal salt solution of varying temperature and quantity, or the betaeucain solution of Lange, is to be preferred to other anesthetic or mordant solutions. Alcohol is harmful and contraindicated. (5) The sciatic nerve may be reached deep in the ischiotrochanteric hollow (its peroneal branch lower down at the capitellum fibulæ), but it is more surely and safely reached directly after its emergence from the notch. (6) The point for puncture and penetration to the nerve is best determined by drawing a line between the posteroexternal border of the great trochanter and the sacrococcygeal joint at the junction of the inner third and outer two-thirds of this line is the spine of the ischium. A thumb's breadth to the outer side of this spine lies the sciatic nerve. Cadaver experiment and clinical experience lead me to endorse this landmark above all others. (7) The method requires a syringe (preferably metal) with a capacity for from 30 to 60 c.c. or more, a needle of desirable length (8 to 12 cm.) directly attachable to the syringe. (8) Accidents of any consequence almost never occur. Unpleasant effects and complications are few and insignificant. (9) The prognosis in the sense of a cure is good if the facts suffice—namely, that in the large number of cases observed for from one to four years many patients have been entirely free from pain during that long interval. Improvement is common. Recurrences are not the rule, and failures are the exceptions."

Deaf-Mutism.—M. M. Stapler gives as the probable mechanism of the production of deaf-mutism by obstruction of the Eustachian tubes (when it is not due to actual destructive labyrinthitis), the fixation of the stapes in the oval window by inward acting pressure on the tympanic membrane. This amounts to a dislocation of the stapes; the stapedius muscle being subjected to extreme tension, becomes paralyzed and the result is deafness, which, occurring in young children, causes deaf-mutism. The reason why we have not

been giving hearing to such deaf-mutes heretofore is that we could not pull the stapes outward and thus reduce the dislocation. Neither inflation nor suction with Politzer's bag will effect this reduction, nor will pulling or punching the tympanic membrane be of any avail. Nature often spontaneously clears the tubes and, as there is considerable freedom of movement in the ossicular chain between the malleus and the incus, the appearances may be apparently normal, the tympanic membrane and the malleus being in their proper positions, but the stapes remain immovable and the tonus of the stapedius still is lost. It has been repeatedly demonstrated, he says, that, when the stapes is put in the right position in these cases, hearing will be restored, and he illustrates a device intended to release the stapes and give hearing in such patients as have not had the stapes bound too strongly by inflammatory adhesions. Several cases are reported in which this apparatus was used with the result of improving the condition of deaf-mutes of the type referred to.

The Lancet, January 30, 1909.

A Typhoid Carrier Successfully Treated by the Inoculation of Typhoid Vaccine.—The essential points of the case treated by S. T. Irwin and T. Houston are as follows: The patient was a maid of twenty-six years, who seven years ago had typhoid fever for seven weeks. On her recovery she resumed her work, but always was easily tired, had frequent headaches, and her stomach was easily disturbed. In the seven years following the fever six people living in the different houses with her fell ill with the fever. It was suspected that she was a "carrier" and she was placed under observation. It was found that the urine contained typhoid bacilli in pure culture and enormous numbers. None was found in the feces. The blood gave a distinct but incomplete Widal reaction. She had a range of temperature from 98° to 100° F. For five weeks she was treated with tonics, urinary antiseptics, and rest, but with no change in her condition. A vaccine was now prepared from the typhoid which had been isolated from the urine. It was injected with the usual precautions. Following the first two inoculations the patient lost a little in weight, had a higher range of temperature, general malaise, and headache, but in the course of three months she returned to a condition of perfect health, while all bacilli disappeared from the urine. The authors call attention to the important fact that chronic typhoid carriers may pass bacilli in their urine and feces only at intervals.

The Parasite of Kala Azar and Allied Organisms.—This illustrated paper by W. S. Patton is of special interest to the bacteriologist. Kala Azar is an East Indian term for the "black death," a fever supposed by some to have a malarial origin and by others to be allied to beriberi. The view that its parasite is a hematozoon cannot be longer entertained. The human system harbors two allies of this parasite and all three are but stages in the life histories of flagellates. The Kala Azar parasite is certainly not a sporozoon, for it remains throughout its life cycle, as far as we know it, a typical flagellate. In its preflagellate stage it may be indistinguishable from a harmless species. This fact is of importance, for in spite of other data the two closely allied human forms, the parasites of infantile splenomegaly and oriental sore, are still regarded as identical with the parasite of Kala Azar.

British Medical Journal, January 23 *and* 30, 1909.

Pyelitis of Pregnancy Treated with Coli-vaccines.—The patient of H. T. Hicks was a young woman of 20 years at the fifth month of her second pregnancy. Symptoms had begun three weeks before admission to hospital, consisting of pain, fever, general malaise, etc., which steadily increased. The urine contained pus, and examination showed a pure culture of the *B. coli*. A vaccine was prepared in the usual way and as symptoms did not improve 10 c.c. of this serum were injected with gradual relief of all symptoms so that in six weeks she was able to leave the hospital. Readmission was necessary in three weeks owing to a return of symptoms, and in due time she was normally delivered. Four days later the urine was clear and had so remained up to the time the case was reported (three weeks). Constipation plays an important factor in the infection of the renal pelvis by the *Bacillus coli*. While the pyuria may persist until the end of pregnancy the virulence of the organisms seems to diminish as soon as the acute stage is over. For mild cases the author finds rest, milk diet, open bowels and potassium iodide and urotropin sufficient; for moderate cases the same routine plus a coli vaccine; in severe cases if the foregoing does not meet the indications the uterus should be emptied. It is not advisable to drain the pelvis of the kidney through the loin because the patients do not stand the shock of the operation very well and moreover if the kidney is itself infected there will be many small foci which cannot be effectively dealt with. By far the best method of securing free drainage is to relieve the pressure of the uterus upon the ureter in the usual way.

Acute Inversion of the Uterus.—A. W. Holthusen reports the case of a primipara of 31 years, who was delivered by forceps under chloroform anesthesia. Uterine action was sluggish, and one hour after delivery the inverted organ with placenta attached was extruded from the vulva. The placenta was easily peeled off and the organ replaced, but if the hand was withdrawn from the cavity it immediately reinverted. Under ergot and strychnine the uterus finally began to contract, bimanual pressure being constantly made. The umbilical cord in this case was only 13½ inches long and it was coiled once around the child's body, thus reducing its practical length to about 6 inches. There was much shock immediately after the original inversion. In all about 2 pints of blood were lost. Recovery was without incident. The author says that when the child was delivered by forceps the fundus was pulled on inadvertently owing to the short cord. After delivery the placenta and its site were further introverted into the cavity of the relaxed uterus by the weight of the child's body exerting traction on the cord. When the uterus did contract the introverted placental site acted physiologically as a foreign body. The uterus then relaxed again and consequently an ordinary post-partum bleeding occurred from the relaxed placental site both before and after its reposition inside the body.

An Experiment in the Treatment of Epilepsy.—D. Goyder refers to a collection of epileptics in a workhouse for whom sodium bromide was ordered to be used as salt in their food, all sodium chloride being carefully kept out. The effect was distinctly satisfactory. It was noted that when the patients came under the full influence of the drug they became listless, stupid, and drowsy, and that then the daily quantity of the bromide used as salt should be diminished one-half, but not altogether stopped. These drowsy symptoms would soon pass off and the patient was again fit for work. The bromide was given in this way not alone at meals, but bread containing it was specially baked for the patients. The author thinks that we do not give large enough doses of bromide in our ordinary treatment of the disease. If eruptions come out we can care for them by cleanliness and appropriate applications.

The Treatment of Pernicious Anemia.—Byrom Bramwell gives notes on one case, his patient being a woman of 54 years. She was placed on five-drop doses of Fowler's solution, gradually but very slowly increased. Her maximum dose was 10 drops. In four months her red cells rose from half a million per c.c. to over four million, hemoglobin from 15 per cent. to 65 per cent., and white cells from three thousand to seven thousand per c.c. She had no dental caries or glossitis and there had been no oral sepsis. The author is inclined to doubt the relative importance of the last-named factor in the production of the disease. The glossitis from which many cases of pernicious anemia suffer is a consequence, rather than a cause, of both being due to the same toxin, whatever it may be, which causes the malady.

Some Reflections Regarding the Free Use of Bacteriological Cultures for the Destruction of Rats and Mice.—J. Danysz refers to the possible danger to human life from the broadcasting of its various microbic cultures for killing rats and mice with a view to stamping out the plague. Actual figures from France show that during the last ten years hundreds of liters of virus for destroying field mice have been distributed each week and that more than a million of people have been concerned in the handling of it. Yet no appreciable case of disease from it has occurred in either man or the domestic animals. The author notes the following points: (1) mice die after having eaten meat and show the bacillus paralyphus B. in the blood, while these organisms could not be found in the meat itself; (2) small and large quantities of food containing this organism have been eaten by human beings without apparent ill effects, and (3) the above organism is found in healthy human blood. He concludes (1) that the microbes of the Salmonella group are extremely widespread in nature, and (2) that if they are frequently found in cases of poisoning through food it is far from being

proved that they are the active agents in these occurrences.

Surgical Treatment of Excessive Axillary Sweating.—F. J. Porter refers to the discomfort of this condition in hot climates and instances the case of an army surgeon who contracted septicemia and had to have made an extensive excision of his axillary glands. Owing to sinuses, it was necessary to remove considerable of the skin and on recovery he found an absence of sweating, and examination showed that all of the hair-bearing skin of the axilla had been removed and along with it the large sweat glands. The comfort to the surgeon was so great that he had a similar operation done under cocaine and adrenalin on the other axilla. The reporter says that the operation is simple, painless, and does not require opening the axilla, and is free from risk. If the suturing is carefully done, the wound heals primarily and the arm may be used in a week.

Treatment of Inoperable Cancer by Hypochlorites.—J. E. Becker reports three cases. The treatment consisted in the injection of a solution of the hypochlorites of potassium and sodium. Five grammes of KOH and four of NaOH were dissolved in a liter of distilled water and passed through washed chlorine gas. Of this solution one and a half to two c.c. were injected daily for a variable period, usually under the skin or over the deltoid muscle or over the great trochanter, so that the solution might enter the system at a site in the general neighborhood of the lymphatic glands. The growth itself and the skin over it were carefully avoided, so also was the use of alcohol during the treatment. An all-glass syringe was used with a platinum needle, ordinary aseptic precautions being taken. Local pain for from two to five minutes followed the injection. No reaction was noted. In the author's cases, one of a pelvic mass found on laparotomy, a second of neck glands following removal of a mammary cancer and the third a carcinoma of the male breast followed by recurrence in the sternum. Good results followed the treatment above described and all the patients were able to resume their respective occupations and are now alive and well. The respective periods since treatment are now forty-four, twenty-one, and nine months.

Treatment of Cancer with Cocaine.—R. M. Gilchrist summarizes the histories of fourteen cases. In every case the general constitutional condition of the patient was very much impaired, even if only for a time. The author says that for the relief of pain cocaine stands unrivalled, for while it eases or takes away the pain, it produces none of the objectionable conditions of opiates. In every case of uterine cancer in which hemorrhage was a prominent symptom, the administration of cocaine was followed by immediate benefit. The author goes so far as to say that he considers cocaine a valuable diagnostic agent, for in case of a doubtful growth he would consider the absence of improvement following cocaine evidence of nonmalignancy. The remedy has been given both internally and externally. The author cannot say whether the remedy has any power over or effect on the embryonic epithelial cell of malignancy whereby a malignant is converted into a benign tissue, or whether benefit arises from the powerful stimulus of the drug. Cancer patients will stand large doses of this remedy.

The Calcium Salts in Various Morbid Conditions.—A. P. Luff gives personal experiences with the calcium salts in the lymphatic type of headache, chillblains, boils, urticaria, facial flushing, aneurysm, hemoglobinuria, edema of the feet on exertion, and various dermatoses. The lactate is the salt most easily taken and is more easily absorbed into the blood than the chloride. The adult dose is fifteen grains, which may be taken in chloroform water with a bit of capsicum tincture added, and it should be given one hour before meals. Constipation commonly follows its use, but as saline purgatives precipitate calcium salts, it is advisable to use some such laxative as senna. Of 121 cases of the various abnormalities above mentioned, 78 per cent. were cured and 9 per cent. considerably improved, while 13 per cent. received no benefit. No bad symptoms followed the remedy in any case. In three cases symptoms suggestive of commencing thrombosis followed the use of the lactate and were presumably caused by it, as they rapidly subsided on its discontinuance.

The Use of Alkalies in Practical Medicine.—Eustace Smith describes the usual effects of the alkalis on the different organs and enumerates various clinical conditions in which they are of benefit. Concerning their action on the stomach, he notes that their long continued use is rarely of service in ordinary flatulent dyspepsia, for, although they are very useful in the early stages, there comes a time when their continued administration ceases to be beneficial. Their chief value consists in their power of reducing an acute or subacute catarrh of mucous membrane. When this has been done and the stomach lining is left flabby and relaxed, a different remedy is required. For all the usual purposes we have the potassium and sodium salts and for many purposes the heavy carbonate of magnesia and carbonate of calcium. In addition to their value in derangements of digestion alkalis are serviceable in the treatment of urinary acidity and the passage of sand or gravel. If bicarbonate of sodium is used for a long time it should be combined with a little salt, for the latter not only aids metabolism, but also increases the vitality and resistance power of the red cells. Too long continuance even of this mild alkali will cause depression. This salt in large doses will sometimes quickly relieve urinary suppression. The alkaline preparations are of use in bronchitis with their viscid secretions. The liquor potassæ is an excellent remedy for this condition. In suppurating finger ends, after the escape of pus by incision or otherwise the bicarbonate of sodium on lint under oiled silk causes the pain and suppuration to disappear with remarkable quickness. It is thought that the effect is due to its local influence in raising the alkalinity of the blood, which has been found to be greatly reduced in cases of febrile reaction set up by bacteriological intoxications.

Münchener medizinische Wochenschrift, January 19, 1908.

Chronic Eczema of Infants.—Feer says that real chronic eczema of infants is a constitutional disease and must be differentiated from various forms of dermatitis that likewise affect infants. The etiology of such eczema depends upon two factors, congenital predisposition and feeding. Two forms must be distinguished, one of them the weeping eczema of the head, the other the disseminated dry eczema. The first usually attacks well-nourished children with a pasty complexion. In addition to the hairy parts of the scalp, the regions of the ears, nose, and cheeks may be affected by the eruption. Hands and arms may likewise show the same lesions. Overfeeding and chronic constipation are the usual concomitants of this, the seborrhoic form of eczema. Improvement and cure usually follow the change from pure milk diet to mixed diet at the end of the first year. The second variety of eczema occurs almost exclusively in artificially fed children. Such children are weak, pale, and thin. The eruption is not as strikingly evident as in the first form, and consists of scattered patches of dry, scaly infiltrated lesions that may be found over the whole body. While local treatment of these forms of disease must be used in every case to make the children comfortable, the cure depends not upon this treatment, but upon changes in the diet of the children. Reduction of milk is the principal point of managing these cases, and carbohydrate food must be given to make up the deficiency in the foodstuffs. After the fourth month of age this is very easy, as the child can be fed on various cereal preparations and also given fruit juice. In later months the albumin of eggs must be avoided, as it is as badly borne as the milk proteids. Whey mixtures may be used in cases where the child is too young to take any other food but some form of milk. The whey may be modified with sugar and cereal gruel, a diet with which Finkelstein had great success in the treatment of eczematous children. Feer concludes his article with the report of a number of cases treated according to the methods outlined above.

Ophthalmoreaction and Prognosis in Pregnancy.—Martin has followed a number of cases of tuberculosis in pregnant women and has studied the relation between the appearance of the ophthalmoreaction and the final fate of the patients. He concludes that in cases of tubercular infection the appearance of the ophthalmic reaction to tuberculin is a favorable sign, the conjunctival injection showing that the body possesses immune bodies acting against the infecting organisms or their toxins. In such cases it is not necessary to interrupt the pregnancy. Negative outcome of the ophthalmoreaction is of very unfavorable prognosis, and in such cases the local lesion and the general symptoms usually progress quite rapidly during the pregnancy. After pregnancy is ended, cure or marked improvement of the tuberculosis may take place, if the interruption has been effected early enough. That such result will always follow induced abortion cannot, of course, always be expected. Total extirpation of the uterus is a justifiable operation in such cases, so that the woman may be protected from another pregnancy during the long convalescence for tuberculous disease.

Deutsche medizinische Wochenschrift, Jan. 14 and 21, 1908.

Resection of Middle Portion of Stomach for Ulcer.—Riedel says that the interest of surgeons has heretofore been turned to ulcers of the pyloric part of the stomach because of the stenosis which such ulcers occasion. However, ulcers of other portions of the stomach are no less important and are almost as frequent, the middle portion of the organ being very frequently affected. These ulcers usually lead to great destruction of the gastric walls even though superficially they appear to be very small. The ulcers of the middle portion of the stomach are situated to the left of the median line of the body and accordingly the pain occasioned by them is felt under the left costal arch and frequently in the back on the left side. As vomiting of blood takes place only in one-half of cases of gastric ulcer, such pain with loss of flesh and strength is often the only symptom of ulcer; in some cases the loss of flesh may not be at all noticed. The diagnosis is assured if a tumor mass develops under the left costal arch; such mass is usually due to the formation of a large ulcer of the anterior stomach wall, which usually becomes adherent to or perforates the left lobe of the liver and occasionally the anterior abdominal wall. Left-sided pain is also present in ulcers involving the mucosa alone; such ulcers may be cured by dietetic ulcer cures, but a chronic thickened ulcer can hardly be affected in this way. However, in every case of ulcer medical treatment should be tried before surgical interference is attempted. Simple excision of ulcer, followed by suture, has been followed with as little good effect as the establishment of a communication between the pylorus and the cardiac part of the stomach anteriorly to the ulcers of the posterior wall. Gastroenterostomy but seldom leads to good results; often it is quite impossible to carry it out because the cardiac portion of the stomach is too much destroyed by the ulcer. It must, however, be performed if the ulcer has spread from the middle portion of the stomach to the pylorus, or if separate ulcers exist at the pylorus or in the duodenum. The best treatment for ulcers in the middle of the stomach consists in the removal of the middle portion of the stomach, together with the ulcer. The result is a stomach that is somewhat shortened in the longitudinal direction, but is otherwise of normal contour and functionates in the usual manner. The prognosis of this operation is favorable, if extreme emaciation or serious disease of the heart and lungs have not complicated the gastric disease. Riedel reports a number of illustrative cases and goes into details in reference to the technique of the procedure and the after-treatment of patients.

Diagnosis and Treatment of Inoperable Carcinoma of the Stomach.—Kuttner says that a most important point in the early diagnosis of stomach carcinoma is always to be on the lookout for the condition whenever stomach symptoms persist for which no other plausible explanation can be given, even if the patient is of youthful age. Occasionally a sudden hemorrhage is the first sign of existing malignant disease of the stomach, the blood being either vomited or passed in the stools. Much oftener, however, the disease begins insidiously with general dyspeptic symptoms, though malignant neoplasm but rarely follows a prolonged disease of the stomach characterized by atrophy of the glandular apparatus. Diminution of appetite is another important symptom of carcinoma, meat being especially distasteful to the patient. The existence of general disposition to the development of the disease—that is, advanced age—must always make the physician on his guard for the probable presence of cancer of the stomach, but age by itself should not be given too high a valuation in differential diagnosis. Family history of cancer must always be given some consideration, though malignant disease is frequent enough without any such history. Trauma plays hardly any rôle in the development of disease. A history of a chronic gastric ulcer is a most important point, speaking for the possible development of malignant disease in scar tissues. Obstinate and intense pruritus has been frequently observed by Kuttner in the early stages of cancer, a symptom that is hardly ever mentioned in text-books. Occasionally a most important symptom is found in the swelling of left supraclavicular lymph nodes; swelling of the umbilical glands usually occurs in late stages of the disease. In addition to obstinate dyspepsia, retching of foul smelling gas, and vomiting of "coffee-ground" material form most important symptoms of the disease. Pain is usually absent and if present has no diagnostic significance whatever. The most important symptom is the appearance of a tumor mass. This may, however, appear only in very late stages or be very hard to recognize because of meteorism or rigidity of the abdominal walls on palpation. If the latter condition is present the patient may be directed to depress the abdominal walls with his own hands as proposed by Skutsch. The appearance of visible peristalsis in the normal or the opposed direction is a very valuable sign of a pyloric tumor. So far as changes in the acidity of the gastric juice and the presence of ferments or of lactic acid are concerned, these symptoms are only suggestive of malignant disease, but may occur in many other conditions. Of great assistance in the diagnosis is the examination of feces or of stomach contents for blood, but the presence of blood in these cases must not be interpreted without much careful study. Often a small amount of blood may be found after the introduction of a stomach tube and this is of a diagnostic significance except in alcoholics or patients suffering from advanced liver cirrhosis, in whom bleeding from the mucosa of the esophagus or of the stomach is quite frequent on very slight provocation. Examination of feces for occult blood must only be carried out after the patient has been on a meat-free diet for a couple of days. Often a nonmalignant tumor may give rise to slight bleeding. The presence of pus, blood, or mucus on examination in the morning before food has been given speaks for cancer; the washings in such cases should be always examined for particles of tumor tissue. The presence of albumin in the stomach contents after the administration of a nonalbuminous test meal should also be looked upon as a symptom of cancer, the secretion of the tumor being rich in proteid. Left-sided pleurisy is an important symptom of carcinoma of the lesser curvature. Immediately after the diagnosis of cancer of the stomach has been made, the advisability of operation must be considered before any other treatment is decided upon. There is no doubt that without a radical operation the prognosis of cancer of the stomach is hopeless, in spite of the claims of many new methods of treatment recently introduced. The treatment of inoperable cancer can only be symptomatic and a most important part of it is the regulation of the diet. No general rules can be given, but in every case the attempt should be made to select such food as will lead to the least possible disturbance because of the insufficiency of the glandular secretions of the motor function of the organ. As an appetizer condurango bark in various combinations with hydrochloric acid and resorcin is quite useful. The presence of foul gas or of food remains indicates very careful lavage with a soft stomach tube, very weak antiseptic solutions being used. Hemorrhage should be treated by stopping all food by mouth and the application of an ice bag to the epigastrium, and the administration of morphine. Constipation is best dealt with by the administration of enemata and of vegetable laxatives. Saline laxatives must be avoided. Diarrhea may be treated in the usual fashion, but frequently lavage is the best means of stopping it.

Infusoria in Stomach Contents.—Cohnheim says that he has found infusoria in the mucopurulent contents of the stomach evacuated early in the day before any food is given; the material was obtained with the use of a warmed stomach tube and the contents were caught in a warmed Petri dish. Six cases were those of carcinoma of the stomach or of the esophagus, while previous to this series of cases Cohnheim found like parasites in six other cases of malignant disease of the upper alimentary canal. The appearance of infusoria, however, is not limited to such disease, as similar findings have been reported in a few cases of benign affections of the stomach, and Cohnheim himself has found infusoria in a case of achylia gastrica. It is probable, however, that such cases are very rare, and the finding of infusoria in the stomach contents speaks very strongly for the existence of an ulcerating carcinoma of the esophagus or of the stomach. The appearance of living infusoria in the feces speaks for the existence of a gastritis of some nature. But all infusoria have no pathogenic character whatever; they simply accompany certain pathogenic conditions in the alimentary canal.

Xanthoma in Icterus.—Posner reports the case of a woman of thirty-seven in whom a general xanthomatosis of the skin developed in the course of a jaundice due to a cirrhosis of the liver. The affection began with a xanthelasma of the eyelids and then spread over the body; it was quite symmetrical in distribution and was especially prominent in the parts of the skin exposed to pressure. A scar

of an old laparotomy wound showed the peculiar pigmentation very well. Each new crop was accompanied by intense pruritus. After reaching a certain stage the well-developed lesions remained for some time without any changes. The treatment by means of mineral waters and baths was quite without any effect, though the patient tried many different watering places.

Acquired Diverticula of the Large Intestine.—Franke says that false diverticula of the bowel are not at all rare, and have a clinical significance as well as pathological interest. They may be found anywhere in the course of the intestines, but are most frequently situated in the sigmoid flexure; their size varies from microscopic dimensions to small pouches the size of a hazel or a walnut, and they may occur singly or in large numbers. The mesenterial side of the intestine is the more frequent site of these pouches, the neighborhood of a large vein being usually affected. Elderly persons have been most frequently found to possess these anomalous structures and in them they form very dangerous affections. The walls of the diverticula may become very thin from pressure of the intestinal contents, and perforation into the peritoneal cavity may occur. Acute inflammation may result in gangrene of the diverticula and the formation of circumscribed abscesses about them. Most frequently, however, there takes place a chronic inflammation of these structures with the formation of abundant connective tissue which on external examination shows a mass and may simulate malignant tumor of the sigmoid. Stenosis of the intestine often results and the feature of malignant disease are still further imitated; frequently regressive changes take place, and it is probable that the few reported cases of the disappearance of supposed intestinal carcinomata may have been such cases. Often the chronic inflammation leads to adhesions to the neighboring organs and symptoms may be referred to these organs and not to the original site of the disease; frequently a fistula results from such adhesions, the bladder being broken into. The clinical symptoms that accompany the various affections of the diverticula are those of any intestinal inflammation accompanied or unaccompanied by peritonitis, as the case may be. The greatest difficulty is offered in the differential diagnosis of some affection of a diverticulum with the formaton of a mass from a malignant tumor. The most important symptom in the latter case is the appearance of blood in the feces in microscopic quantities at first and later in larger quantities; such bleeding is much more rare in case of benign affections of the diverticula. Beyond this, later stages of malignant disease bring with them distinctive picture, but in the early stages exploratory operations are often called for so that the nature of the trouble may be learned. Beyond medical conservative treatment, which in many cases may bring very great improvement in symptoms, surgical treatment offers most in dealing with affections of the diverticulæ. In most cases resection of a portion of the intestine, in other simple colostomy is indicated.

French and Italian Journals.

Case of Myomectomy in Pregnancy.—Vincenzo Valdgni says that the prognosis of myomectomy in pregnancy improves with time, and knowledge. It differs with the nature of the fibroid, whether pedunculated or sessile, since the uterine muscle is less stimulated to contraction by the removal of a small pedunculated growth than when it is necessary to enucleate a tumor that is deeply implanted in the muscle. Cases of this complication of pregnancy are rare. In most cases the termination of pregnancy can be avoided. The indication for removal is obstruction to the delivery of the child by the size or position of the growth. In some cases with the growth of the uterus the tumor is carried upward out of the way, or at the time of labor the uterine contractions push it upward. We must consider the relative risks of abortion as a result of the presence of the tumor, and of abortion as a result of operation for the relief of the condition. The frequency of abortion in fibroids complicating pregnancy is variously estimated at from nine to thirty-six per cent. The frequency of abortion after myomectomy is eleven per cent. according to the statistics of the author. Hence it would seem that abortion is more likely to occur when the fibroma is left in place than when it is removed. The life of the mother must be considered as well as the risk of abortion. The technique of removal is the same as in other conditions of myoma. The uterus should not be drawn out of the pelvis nor traction made upon it. In the author's case the tumor occupied the right horn of the uterus, and was the size of a hen's egg. The indication for removal in this case was extreme pain and threatened abortion. The operation was done at the fourth month of pregnancy, and delivery occurred normally at the end of nine months, with a living child.—*La Ginecologia*, October 15, 1908.

Diagnosis and Treatment of Atonic Gastrectasia.—Paul Carnot advocates in the treatment of atonic gastrectasia measures that are simple as well as practical. He places the patient at the time of digestion in a position in which the pyloric portion of the stomach will be dependent, and thus the food will not collect in the dependent portion and stagnate, as would be the case in the sitting or standing position, but will tend to pass out of the pylorus as soon as it is digested, and thus fermentation will not occur. For this purpose, after the patient has eaten, he is instructed to lie down for two or more hours on the right side; this position causes the pylorus to assume the lowest position, and the food passes quickly out of the stomach when digestion has taken place. To facilitate this form of treatment he instructs the patient to eat his heaviest meal at night, and to lie down after it. He also limits the diet to articles that will be as far as possible digested rather in the intestine than the stomach; this will avoid overfilling it with material that must be digested in the stomach. A stomach treated in this way soon begins to function better and the patient's nutrition becomes better. Later on more albuminoids are given, when the stomach acts better. It is found that a stomach treated in this way becomes less liable to stretching from the weight of the food, and thus eventually a cure is effected without the patient being obliged to give up a fairly active life. In some cases it is necessary to begin the treatment with rest in bed for some weeks.—*La Presse Médicale*, October 28, 1908.

Operative Indications in Biliary Lithiasis.—E. Quénu says that it is recognized among surgeons that operation is not justified in all cases of biliary lithiasis; in some cases it is not only indicated but urgently demanded. In many cases the symptoms are so slight as not to have been noticed by the patient, and yet stones are found in the gall-bladder at autopsy. A large number of examples of lithiasis are compatible with nearly normal health. Even the *x*-rays do not aid much in diagnosis. The uncertainty of diagnosis demands reserve in operation. There are several arguments for early operation in the absence of severe complications; the benignity and simplicity of operation, the possibility of preventing the invasion of the large bile ducts by infectious complications, the prevention of the undoubted predisposition to cancer that lithiasis causes. Danger begins with the migration of the calculi. Some authors claim that it is best to avoid all complications and suffering by removal as soon as diagnosis is made. On the other hand, many patients after a single attack of colic return to a condition of latency. The author believes that operation should be justified by complications, accidents, or the exaggeration of pain. Acute cholecystitis is believed by Körte to be an absolute indication for operation. In a grave crisis operation may be urgent. When infection has become generalized, kidneys are affected, and there is pulmonary congestion and endocarditis surgical interference is contraindicated. In milder attacks we should seek to control the inflammation by cold and rest. In chronic cholecystitis there may be continual pain and tenderness on pressure, bad digestion, emaciation, and bad general health. Here we should operate for the comfort of the patient. Hydrops is only a relative indication for operation. Chronic empyema is an absolute indication. Hepatic colic of ordinary type does not necessitate operation, but when there is cholecystitis it is demanded. In either cases leave treatment to the physician. In obstruction of the cystic duct by a calculus that grows slowly a spontaneous cure is rare, even by ulceration. Early operation gives the best results, and delay gains nothing.—*Revue de Chirurgie.*

Twenty Cesarean Sections at the Lariboisière.—E. Bonnaire reports twenty cases of cesarean section occurring in one thousand labors at the Lariboisière in his service. He believes that a defect in physical culture in the earliest years has much to do with the occurrence of contracted pelvis. Cesarean section was never done by the author when there was any other recourse to save mother and child. In one case the dying mother was operated on to save the life of the child, which lived ten weeks. Another was done for obstruction of the pelvic canal by inoperable cancer. The eighteen other operations were conservative. In four there was an absolute indication for the operation. Obstruction by cancer, cyst, cicatricial atresia, adnexial tumor, or malformation of the pelvis necessitated delivery by this method.—*La Presse Médicale.*

Book Reviews.

American National Red Cross Textbook on First Aid and Relief Columns. A manual of instruction how to prevent accidents and what to do for injuries and emergencies. By Major Charles Lynch, Medical Corps, United States Army. Prepared for and endorsed by the American National Red Cross. With 74 illustrations. Philadelphia: P. Blakiston's Son & Co., 1908.

This little work on first aid is calculated to be very useful. It is clearly written by one who understands the requirements of the case, and it should appeal to a very large number of readers. There are a dozen chapters in the book, dealing with the following subjects: Anatomy and physiology; germs and microorganisms; first aid materials; general directions for rendering first aid; shock; common accidents and injuries; common emergencies; occupation accidents and injuries; injuries and emergencies of indoor and outdoor sports; transportation of wounded, injured, and sick; organizations for first aid instruction; and first aid contests. The volume concludes with a list of references and an index.

A Dictionary of Medical Treatment. For Students and Junior Practitioners. By Arthur Latham, M.A., M.D., Oxon., M.A. Cantab., F.R.C.P. Lond.; Physician and Lecturer on Medicine at St. George's Hospital; Senior Assistant Physician to the Brompton Hospital for Consumption and Diseases of the Chest; Advisory Physician to the Throat Hospital, Golden Square; Advisory Physician to the York Road Lying-in Hospital. Philadelphia: P. Blakiston's Son & Co., 1908.

The object of this little book is to supply beginners with an outline of treatment which is at present in vogue. The author realizes that this crystallization of methods leads to a dogmatic style, but in a work of this size and scope such a drawback is unavoidable. The subject matter is arranged alphabetically, thus making it an excellent ready reference book. It is printed on thin paper and bound with a flexible cover, and is of such size as to make it easily portable. The author has seen fit to include only medical subjects, wisely leaving surgical diseases to other treatises. Throughout a conservative attitude is taken, and some of the newer methods are ignored, probably due to lack of space and the author's lack of belief in their use as being other than problematical. He advocates tuberculin in minute doses, 1/20000 mgm. to 1/5000 mgm. His technique in the Nauheim baths is inaccurate, but safe. His advice is not confined to medicine, but deals largely with hygiene, general management, and physical aids, such as the modern therapeutist advocates. As a whole, it is a satisfactory compend of the methods of to-day.

The Popes and Science. The History of the Papal Relations to Science During the Middle Ages and Down to Our Own Time. By James J. Walsh, M.D., Ph.D., LL.D., Professor of the History of Medicine and of Nervous Diseases at Fordham University School of Medicine; Professor of Physiological Psychology at St. Francis Xavier's and Cathedral Colleges, New York, and Lecturer on Biology at the Catholic Summer School of America. New York: Fordham University Press, 1908.

The author of this most readable and astonishing book was led to write it by the discovery that the general belief that the Popes and the Church had always been inimical to science was not borne out by the facts of history. The Galileo incident he admits, and says there is no doubt that this scientist was prosecuted (he does not say persecuted) by the Roman inquisition on account of his astronomical teachings, and he concedes that it was a deplorable mistake. It was, however, more because of the way in which Galileo urged his truths than because of the truths themselves that he was condemned, and Dr. Walsh quotes Cardinal Newman, who said that this very case proved that the Church did not set itself against scientific progress, for this was the "one stock argument" of those who would have us believe the contrary. As a result of his studies in medical and ecclesiastical history the author found, he says, that the supposed Papal opposition to science was practically all based on an exaggeration of this one incident, and that, as a matter of history, the Popes were as liberal patrons of science as of art.

The limits of a review notice do not permit us to follow Dr. Walsh's masterly presentation of the Papal side of the controversy, and we can only indicate a few of the points that he appears to prove beyond the power of contradiction. In the matter of dissection he shows by documentary evidence that not only did the Church not forbid dissection, under proper restrictions, but even granted anatomical privileges when the civil authorities refused them. Chemistry also—not alchemy—received the support rather than the opposition of the ecclesiastical authorities. The Popes fostered schools of science and medicine, no less than four of which were in the Papal dominions, and two of them—Rome and Bologna—were during several centuries the greatest medical schools of the world. Pope Innocent III was the father of municipal hospitals, and the Church founded and maintained many of the greatest and most complete general and special hospitals of the time. All these facts are proved by quotations from non-Catholic historians, and writers on medical history especially, and also by transcripts of papal bulls and decrees.

The book is more or less controversial in tone, but this could hardly have been avoided since its object was to refute the statements of those who maintained the opposition of the Church and of the Popes to science. But while the author is vigorous in his denunciation of what he holds to be false statements, he is not bitter or unfair, and his writing is happily free from all taint of the odium theologicum. Entirely apart from controversy, the book is in itself most interesting and readable, and constitutes an original and exceedingly valuable contribution to the history of medicine.

Aids to Ophthalmology. By N. Bishop Harman, M.A., M.B., Cantab. F.R.C.S. (Eng.), Ophthalmic Surgeon to the Belgrave Hospital for Children; Chief Clinical Assistant, Royal London Ophthalmic Hospital, Moorfields; etc. Fourth Edition. New York: William Wood & Company, 1908.

In the present revision this book has been enlarged by about seventy pages and forty new illustrations. The sections which show the most change are those on External Diseases, Refraction, Squint and Muscular Disorders. There are new chapters on the Examination of the Eye, Diseases of the Orbit, Diseases of the Sclera, Amblyopia and other symptoms of Focal Disease, and on the Eye Conditions of School Children. The work was originally written by Mr. Jonathan Hutchinson, Jr., and under the new editor it will doubtless continue to enjoy the popularity which it has so well earned.

Traitement de la Tuberculose par la Paratoxine, basé sur l'action antitoxique du foie. Par E. Gerard, Professeur de Pharmacie et de Pharmacologie; et G. Lemoine, Professor de Clinique Médicale à Université de Lille. Paris: Vigot Frères, 1907.

The authors here give their results and beliefs in the use of paratoxine. This substance is a mixture of cholesterin and biliary extract with petroleum ether boiling at 113° F. This forms a mixture of the above ingredients in which can be found lecithine, oily bodies, and a nitrogenous body. The method of administering is usually hyperdermic and the experimenters claim that it may be given with distinct benefit to the tuberculous patient.

Cataract Extraction. By H. Herbert, F.R.C.S.; Late Lieutenant-Colonel, I.M.S.; Professor of Ophthalmic Medicine and Surgery, Grant Medical College, and in charge of the Sir Cowasjee Jehangir Ophthalmic Hospital, Bombay. New York: William Wood & Company, 1908.

Those familiar with the first book on the extraction of cataract by Colonel Herbert are acquainted with the ability and fairness of the author. The present volume is one of 391 pages, is well printed, and sufficiently well illustrated. The operations for the extraction of cataract are described in great detail. The different forms of operable cataract, the preparation of the patient, the selection, sterilization, and use of instruments, and each step of the various operations are very minutely described. The difficulties that are met with in regard to the position of the eye, whether prominent or deep, the condition of the conjunctival sac, whether normal or reduced by cicatricial contraction, are discussed. The various forms of the incision are described and passed upon. The difficulties in making the incision, in performing iridectomy, in making the capsulotomy, expressing the lens substance, removing the cortex, and in performing the toilet of the wound are carefully described. The dressing and after-treatment are given full mention.

The accidents attending and following operations are enumerated and described in full. The value of various procedures in dealing with these complications is discussed. In fact, the work is a complete consideration of the question of cataract extraction treated exhaustively by one of large experience and recognized ability. There is much of the personal element in the volume, but this is not expressed to the detriment of authors whose opinions are entitled to respect and careful consideration. Those who operate on cataract cannot but be greatly benefited by reading this very excellent treatise.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held January 21, 1909.

THE PRESIDENT, DR. JOHN A. WYETH, IN THE CHAIR.

Cancer of the Breast.—Dr. W. L. RODMAN of Philadelphia presented this paper. He said that he was of the opinion that the arguments of those who saw nothing in carcinoma but a germ disease were, to say the least, inconclusive. Where the disease was strictly local, an early diagnosis made operative cure not only possible but highly probable; on the other hand, a tardy recognition of mammary carcinoma could not be atoned for by the most brilliant operative procedure. The transition from a local and easily operable condition to a general disseminated and inoperable one might take place quickly. Cancer began as an undue proliferation of the epithelial cells of the mamma and continued to be a strictly local neoplasm if operated upon before metastases had occurred in the neighboring or distant lymphatic glands and viscera. Early operation would cure 80 per cent. of all cases without glandular involvement, but it could also be demonstrated that infection of even the nearest lymph nodes, the axillary, permitted of permanent results in only 25 per cent. of such cases. If the laity could be taught that mammary growths were usually malignant and should be treated as such until proved to be otherwise, the operative results would be far better than they are at present. If the disease were as painful at first as it was later, more would seek aid early. Dr. Rodman had encountered only one case in which sarcoma and carcinoma were undoubtedly present in the same specimen. In 232 cases operated upon at Johns Hopkins Hospital, out of 64, where there was undemonstrable glandular involvement, 51, or 80 per cent., were free from recurrence at the end of three years. Of 110 cases with demonstrable axillary involvement, only 24.5 per cent. were free from recurrences at the expiration of three years. Of 236 cases with palpable axillary involvement before operation, operated upon in the Massachusetts General Hospital during the decennium 1894 to 1904, only 12 per cent. were cured by operation. Of 117 cases operated upon in the same hospital where no glands were felt in the axilla, 29 per cent. were cured. The experience at these and other hospitals had demonstrated forcibly that where axillary involvement was so great as to make resection of the axillary vein necessary, the operation had not given a single cure. It was never safe to assume that enlarged axillary glands did not exist; a thorough dissection of the axilla was just as important as the removal of the breast itself. According to the statistics of the Massachusetts General Hospital, 45 per cent. of the cases with adhesions of the growth to neighboring structures, especially the skin and pectoral walls, 11 per cent. passed the three-year limit without recurrences. Of 194 cases without adhesions to the chest walls, there were 41 successful cases, or 21 per cent. Of 262 cases with adherent skin, only 42, or 16 per cent., were cured by operation. In 71 cases in which the skin was not adherent, 37 per cent. were cured. Consequently, this complication was of great importance. Out of 40 cases with palpable neck involvement, two were found to be free from carcinomatous involvement and were well three years after the operation. The remainder, or 38 cases, were fatal. Of 40 operative cases at the Johns Hopkins Hospital, with positive involvement of the neck and axilla, 3, or 7.5 per cent. were cured. Involvement of the neck might occur early in the history of cancerous growths located in the upper hemisphere of the breast, as a chain of lymphatics passed over the clavicle and did not connect with the axilla at all. Ulceration of the skin was a grave prognostic sign. Of 316 cases without ulceration, 31 per cent. recovered. Of 31 patients operated upon after ulceration had occurred, Wunderli reported that but two were living at the end of three years. In cancer of the breast the duration rarely exceeded thirty-six months after the inception of the growth. The more abundant the cellular and the less pronounced the fibrous element, the greater would be its deadliness. Cancer *en cuirasse* was invariably fatal, and was not amenable to any operative procedure. The prognosis for Paget's disease was not good, even if an operation was performed. Women in whom cancer attacked both breasts succumbed quickly. The question as to how long a patient must go without recurrence before she could be considered cured was open to difference of opinion. Dr. Rodman thought that the period should be extended to five years. In the decennium from 1870 to 1880 the best operators only claimed 9.5 per cent. of cures. From 1880 to 1890, S. W. Gross of Philadelphia and Sir William Banks of England claimed 21.5 and 21 per cent. of cures, respectively. From 1890 to 1900 the rate of cures was increased; Dr. William T. Bull had had 26.6 per cent. of cures. F. S. Dennis reported a series of cases in 1891 with less than 1 per cent. mortality, 5 per cent. local recurrences, and 45 per cent. passed the three-year limit; in 1905 he reported a smaller series yielding 77 per cent. of cures. Dr. Rodman thought that at least one-third of the patients coming to operation should be cured and that early cases should give a much better prognosis. He had operated upon more than one hundred cases of mammary cancer in the period from September 1, 1898, to September 1, 1908. Seven out of 25 private patients were dead and one was living with recurrence; 17 were living and in good health, without any evidences of recurrence. In 2,133 cases operated upon by American surgeons, the operative mortality was less than 1 per cent. In operating the advantages of first attacking the axilla were: (1) The axilla might be so hopelessly involved as to make an attempt at removal worse than useless; the sooner this was known the better. (2) The blood-vessels could be reached and tied at their origin, which materially lessened both hemorrhage and shock, as the same vessel was not repeatedly cut as in working from the breast toward the axilla. (3) The axillary space was dissected from above downwards instead of from below upwards, because it was easier from a surgical, and better from a pathological standpoint, since the dissection was begun beyond the encroachments of the disease. (4) They avoided largely the danger of spreading cancer cells to the adjacent tissues. This was a real, and not a chimerical danger, so much so that unnecessary handling of the infected tissue should be avoided. (5) A dissection *en masse* was sometimes made impossible if the work was begun at the sternum, as the heavy mass might pull upon and break the axillary tail. (6) The functional use of the arm would be better because in beginning the incision at the axilla instead of ending there, greater precision was assured. The incision should not extend into the arm; in such a case the cicatrix sometimes restricted the future movements of the arm.

Cancer of the Breast.—Dr. MAURICE H. RICHARDSON of Boston read this paper, in which he said that treatment of cancer of the breast required the most thorough excision; the use of other methods of treatment in operable cases seemed to him wholly unjustifiable. There was little, if any, encouragement that methods would soon be found to replace the knife. He had seen an appalling number of cases become inoperable under these methods which might have had some scientific basis, but which proved as useless as Christian Science. There was a wide field for the trial of nonoperative methods without taking cases that were easily operable. The layman and many physicians did not know this. The watchword of the profession of late years had been "the earliest possible operation." Dr. Richardson

based his remarks upon his own experience. An incomplete search of his records gave 1,300 cases of breast tumor in his practice since 1890. The glaring need in cases of breast cancer was early recognition. His records were filled with cases of cancer discovered too late. The diagnosis of breast tumor might be easy, difficult, or impossible. The treatment was clear in the sure case but uncertain in the doubtful one. Excision was the treatment for all breast tumors at all ages. Pain as a diagnostic sign had but little weight; as an indication for operation it should have only the weight of its own severity. He was forced to the position that no man's experience was adequate to justify the neglect of surgical exploration, when the signs pointed, in the earliest stages, to a possible diagnosis of cancer. The influence of heredity on a doubtful diagnosis should be great. A single case of cancer in a family might be sporadic, but two, three, four or five meant more than the accidental infection from outside the family of one individual. Cancer of both breasts, occurring independently, was extremely rare, but it had happened often enough to mar the diagnostic value of such an occurrence. The only safe rule in dealing with breast tumors was to treat them as malignant until they were proven benign. An examination of the axilla was prolific in important evidence for or against cancer. The presence of perceptible axillary lymph nodes added an evil significance. The presence of supraclavicular lymph nodes of all the metastases was more serious, and the most malign signs were those of involvement of the cerebrospinal axis. Any persistent cerebral or spinal symptom should excite the strongest apprehension. A persistent cough without adequate signs in the lungs added strength to the diagnosis, although it weakened the indications for operation. Dr. Richardson believed that a tumor doubtful enough to justify the use of the punch or knife section for the microscope should be immediately extirpated, for he was convinced that autoinfection in all forms of malignancy was possible. The prognosis for cancer unoperated upon was as bad as it could be. Statistics based upon a surgeon's own experience were the only ones that were of any value in the formation of his own prognosis. When there was a mass of conglomerated lymph nodes in the axilla, even if there were none perceptible at the first rib, he knew that his dissection was probably too late. When he found but one or two nodes in the center of a mass of axillary fat, easily separated by an extensive and clean dissection, he knew that the outlook was bright for the patient. Surgeons probably erred most frequently by giving a too favorable prognosis. He did not think that there was any limit of years after which a patient might be said to be cured. In favorable cases the probabilities of recurrence were influenced by the thoroughness of extirpation. Except for pain and annoying discharges, the prognosis in advanced cases of mammary cancer was such as to forbid operation. The only exceptions to the rule of universal exploration were those cases of multiple tumors affecting both breasts, which were unmistakably retention cysts. A breast tumor appearing after the removal of a benign growth or simple cyst was another exception. Still another was the appearance in the other breast of a tumor like a benign one that had been removed from the first. Barring contraindications, such as might be found in other organs and in certain constitutional diseases, a better rule was the removal of every tumor of the breast, of whatever nature, at any age. This was the only way to avoid those errors, which, however infrequent, were nevertheless so appalling and indefensible.

Cancer of the Breast.—Dr. Willy Meyer said that early operation depended upon an early diagnosis. The diagnosis of scirrhus carcinoma was comparatively easy, but the diagnosis of adenocarcinoma was difficult This had no effect upon the nipple, its growth was diffuse, simulating that of adenofibroma, and it certainly was not an easy task to diagnose adenocarcinoma in its incipiency. To confound it with the so-called diffuse interstitial fibroma, or chronic mastitis, was hardly possible. The diffuse fibroma belonged to the borderland cases. A suspicious adenofibroma, however, required prompt radical operation. Dr Meyer had had a number of cases of suppurative mastitis, showing a diffuse, hard swelling, which had developed after nursing and had persisted for some time, with now and then some tenderness; these patients were sent to him with the diagnosis of carcinoma. Simple incision effected a cure in these cases. To remove such a breast on the basis of the possibility that the long existing inflammatory focus might produce a malignant growth, would certainly be going too far in their desire to be radical. In making the diagnosis in tumors that admitted of doubt as to their malignancy, the surgeon should never forget the use of the aspirator, which would draw pus in these instances, a fluid that carcinoma never harbored. All of Dr. Meyer's cases were operated upon by the same procedure which was published in the Medical Record, December 15, 1894. Its principal characteristics were that the affected breast, together with the two pectoral muscles, plus axillary and subclavian glands and surrounding fat, were lifted out in one mass All incisions were made within healthy tissue. The work was done from the axilla toward the breast. Blood-vessels were promptly divided at their exit from or entrance into the axillary vessels. The lymphatics were first cut out before the seat of the disease was approached. The operation was typical, anatomical, simple, and was accomplished with a minimum loss of blood. The various operations devised by others, with the exception of the Halsted operation, were all based on the principles laid down in his operation. Dr. Halsted published his procedure simultaneously with the publication of Dr. Meyer's, in the fall of 1894. Dr. Meyer reported the case of a woman, now sixty-four years old, upon whom, in July, 1900, he did a radical operation for an ulcerating scirrhus in the outer lower quadrant of the breast. For eight years the patient remained in perfect condition. He considered her one of his star cases, inasmuch as she seemed to be in such perfect health the entire time and enjoyed absolutely unencumbered use of her arm. In May, 1908, however, she returned to him with a small tumor over the cartilage of the second rib. She had observed it for the last two and a half months. An examination showed a local recurrence, slightly movable. When he operated a few days later the tumor appeared to be sessile on this cartilage, involving the adjacent part of the sternum, and to be diffusely connected with the surrounding tissues. As much of the growth as possible was lifted out with the aid of a broad, grooved chisel and the wound closed without drainage. He expected a prompt continuance of the disease because of the cancerous elements that he had to leave behind. The wound healed by primary union. In the absence of better means he had her use a large oval, Bier's cup daily for forty-five minutes over the sore and, in addition, had her treated with *x*-ray exposures three times a week. After seven months the tumor had not recurred, but the subclavicular glands were recently found to be involved. He did a very extensive removal, but found the entire supraclavicular space badly involved. In view of this state of affairs, he said he could not but think that, had the supraclavicular space been cleaned out thoroughly in 1900, this patient might perhaps have been saved. He found now she could live but a very short time In his summing up he said that surgeons might hope to improve their results by an early operation, based on early diagnosis, by educating the public to understand that the painlessly developing tumor was the most dangerous, by operating also upon circumscribed apparently benign tumors which might become malignant, and by finding the cause of carcinoma

Dr. Arpad G. Gerster said there was one tumor of the breast which could be diagnosed before operation and which did not require amputation, *i.e.* gumma, for which amputation of the breast had been and was being unnecessarily performed. He believed that no mammary tumor should be attacked by the knife until the diagnosis of syphilis had been set aside. He had seen twelve cases in which iodide of potassium caused such tumors to disappear entirely.

Dr. William B. Coley said that he had observd 140 cases of carcinoma of the breast, and that he had as yet not seen a single case of gumma of the breast. He thought it would be a loss of time to subject the patient to a course of treatment with iodide of potassium. In nearly all the cases of local recurrences the infection was caused by the cancer cells that were left behind, rather than by a reinfection. This same explanation applied to the metastatic cases as well. With regard to the benign and borderland cases, Dr. Gibson at the New York Surgical Society gave the correct opinion. One should operate in all such cases, especially after the age of thirty-five years. Two and a half years ago a woman, forty-eight years old, was referred to him. She suffered from some spinal disease and she had a small, apparently benign tumor of the breast. The tumor was not larger than a pea, was movable, and quite characteristic of fibroadenoma. The pathologist pronounced it to be a typical adenoma. This tumor was removed. One year later a similar tumor appeared to one side of the cicatrix. This was removed and the pathologist said it was almost entirely an adenoma, but there were a few cells with carcinomatous changes. The entire breast was then removed. One year later there were recurrences in the opposite breast and the patient had since died of carcinoma of the pectoral muscles and of the neighboring glands.

Dr. Algernon T. Bristow spoke of the difficulty of making an early diagnosis in these cases of breast tumors, and reported the case of a woman, thirty-seven years old, who came to him with a small tumor in the upper external quadrant of the breast. There was absolutely no dimpling of the skin; the tumor was freely movable. Under nitrous oxide gas a portion of the tumor was removed, frozen, and given to the pathologist for diagnosis. Ten minutes later the report came back that it was a benign tumor. Dr. Bristow was putting on the dressings when a hurried message came from the laboratory that the pathologist had found an area of the tumor carcinomatous. The anesthesia was again given, and the tumor was removed. This was eighteen months ago, and the patient to-day was apparently well. He always advocated the use of the *x*-ray as a prophylactic after the operation in these cases.

Dr. John A. Wyeth thought that much could be accomplished if the patients were convinced that the operation of removing these tumors was practically without danger, and if they were taught that many of them would be saved by early operation.

SECTION ON PEDIATRICS.

Stated Meeting, Held December 10, 1908.

Dr. Godfrey R. Pisek in the Chair.

Webbed Hands and Feet.—Dr. Henry W. Frauenthal presented a child with congenital webbed hands and feet. All the digits of the hands, including the thumb, were absolutely webbed together. There was also an absence of the soft palate. The child was five months old and nursed well.

X-Ray Pictures of a Case of Infantile Scurvy.—Dr. E. A. Riesenfeld made this presentation. He reported the case of a baby, ten months old, whose history before the date of examination was negative, and whose family history also was negative. The baby was born at full term and the labor was normal. The child was very restless for six weeks previous to its presentation at the hospital, crying almost continually, and especially when the lower extremities were handled. The physical examination showed a child in fairly good general condition, with excessively tender and relaxed limbs; the examination of the oral cavity was negative, the liver and spleen were both palpable. The baby was put upon a raw milk mixture with the addition of fruit juice; this was followed by a rapid improvement. The tenderness of the limbs had almost entirely disappeared after twenty days' treatment. The weight rapidly increased. Dr. Riesenfeld said that in those cases of Barlow's disease where many of the cardinal symptoms were absent or obscure, the *x*-ray proved a valuable aid in the diagnosis, enabling one to trace those changes in the bone resulting from and following the correct treatment of the condition. The *x*-ray plate revealed two important conditions, subperiosteal hemorrhage, and changes at the epiphyseal line.

Dr. Thomas S. Southworth said that in cases of such pain occurring in children who had a history of being fed with artificial food and water, the diagnosis of scurvy was easily made. He had had three such cases during the past year.

Dr. Godfrey R. Pisek said that although the *x*-ray was very valuable to the general practitioner, frequently in these cases of infantile scurvy the diagnosis was not made, and unfortunately these children were treated for other conditions while the true nature of the disease was not thought of. When used, the *x*-ray was only confirmatory of the diagnosis already made.

Hemorrhage in the Newborn, Apparently Due to Delayed Coagulability of the Blood Transfusion.—Dr. Herman Schwarz and Dr. Reuben Ottenberg reported an unusual case in which blood transfusion was performed in a newborn child. The child was born at full term and the labor was normal. The baby was apparently well until the seventh day when he began to vomit after feeding. On the eighth day the vomitus contained blood, and blood was noticed in the stools. On the tenth and eleventh day bleeding occurred from the mouth. There was no skin eruption, and the liver and spleen were palpable. The lymphatic glands were not enlarged. After the birth of the baby, the mother developed an abscess of the breast which was almost healed. Ten c.c. of horse's serum was injected subcutaneously, but this failed to have any effect upon the bleeding. It was learned that the baby's blood coagulated in forty-eight minutes, and the father's blood in from four to five minutes. If a portion of the father's blood was added to a portion of the baby's blood, the coagulation time was reduced to the normal. The addition of the calcium salts had no effect upon the coagulation, and so transfusion was decided upon. At the time operation was decided upon the hemoglobin was 40 per cent. and when the child was placed on the operating table, it was reduced to 30 per cent. The father furnished the blood for the transfusion. At operation the child appeared to be dead. During the transfusion the hemoglobin increased from 30 to 90 per cent. and all in the course of twelve minutes. When the latter percentage was reached the transfusion was stopped. So soon as the child got the father's blood, the bleeding immediately ceased, and the coagulation time was practically normal. For five days after the operation the bleeding ceased; then bleeding began again. The child died on the twenty-first day as the result of the continued loss of blood.

Dr. F. L. Wachenheim asked Dr. Schwarz when this method of treating hemorrhages was first suggested.

Dr. Schwarz replied, in 1905.

Dr. Wachenheim said that he antedated that time by two years, because he suggested this same treatment in

1903. In these hemorrhages it was probably the complement which must be supplied; this could be done by the use of any foreign serum, as he had advocated in 1903.

Infant Mortality: Comparison of the Past and Present.—Dr. William L. Stowell read this paper, in which he said that statistics had only been collected in civilized countries during the past generation and hence it was only recently that comparison of the past and present was possible. He had made the present study for the purpose of finding out wherein gain had been made and wherein loss had taken place so that it would be possible to lay plans for future work. He thought that infant mortality could be considered as beginning before birth, and Guillemot and Devillieres claimed that from 20 to 25 per cent. of pregnancies failed to mature. In 1851 to 1860 the birthrate in England was 43.1 per 1000 population, while in the United States it was 33.6 per 1000 population; now it was 28.1 per cent. in England and Wales and 27.2 in the United States. The decline was relatively the same in other civilized countries except in France, where it had fallen to 22.2 per thousand. Illegitimacy was also a factor in causing infant mortality, as illegitimate children showed a very high deathrate, due to neglect and to the fact that this class of children was so often sent to institutions. The number of illegitimate births in England had fallen from 6½ per thousand in 1860 to 3 at present. Deformities such as spina bifida, hydrocephalus, etc., lessened the liklihood of children living beyond infancy. Unfavorable constitutional tendencies that lowered the powers of resistance, habits and morals of the parents that were visited on the children, also increased the infant mortality. In studying infectious diseases it was found that the number attacked increased in proportion to their exposure outside the home. Pneumonia carried off a large number of infants; in 1906 more than 12,000 infants died from this disease in the registration area. It could be questioned whether physicians were treating pulmonary and diarrheal diseases as wisely and successfully as they were treating the infectious fevers. The mortality rates in different countries and in different years were so divergent that they could only be explained by studying the character of the homes, the methods of caring for children, and the habits and lives of the mothers. In the year 1860 in this country there were 207 infant deaths out of every one thousand deaths, in 1900 only 191, while in 1906 there were 202. This seemed to show very little gain since 1860. He had presented the records of the Infant Hospital as a basis for his opinions as regards to the effect of certain methods of caring for children upon the mortality. This institution, which was founded in 1866, showed during the first five years of its existence a mortality of 55 per cent. for all children admitted; the mortality for the mothers' children was 16 per cent. The next five years showed orphans and foundlings with a mortality of 44.6 per cent., while the mortality of mothers' children was 12.4. It seemed to be the universal rule that mothers' children had about four times the chance of life that the orphan and foundling had. The mortality among babies farmed out was 14 per cent. in 1875, 21 per cent. in 1885, and 48 per cent. in 1888. The rates for farmed out infants fluctuated markedly, but in general they were lower than for infants kept in the institution. The average mortality of the foundlings from 1897 to 1901 was 47 per cent., a gain of eight points as compared with the five years from 1868 to 1872. Children had been fed with various proprietary foods at different times, but in the main milk was used. After the introduction of new methods in the hospital in 1891, competent nursing, sterilized milk, an increase in the number of wet nurses, renovation of the buildings, sending of contagious diseases away from the Island, and finally, in 1898, the introduction of the percentage method of feeding, the mortality rate for the year 1898 was 19.8 per cent. Since that time it had never risen higher than 27 per cent. Overcrowding had a direct effect upon mortality and this increase was greater among young children. Statistics for the cities and counties in New York State showed that in 1901 there were 70.9 deaths per thousand population in the cities to 39.8 in the country. There had been a steady advance in both city and country during the succeeding years. Density of population alone was not necessarily a reliable standard, as in the Ansonia, New York's largest apartment hotel, where there were 2,000 persons living in 2,500 rooms, making a density of 1,262 per acre, where everything was modern and hygienic, there had not been an infant death in the seven years since the building was completed, neither had any employee, of which there were 400, given up work because of tuberculosis. This showed that it was possible to have a dense population without a high deathrate. In the tenement districts the smaller the number of rooms the higher the deathrate. Dr. Stowell quoted from a paper written by Dr. Harris in the beginning of the eighteenth century in which he scored the women of that day for their failure to nurse their children and their preference for cards, theaters, and social diversions. The women of today were but a replica of their forebears. When the factories were closed in the South during the Civil War there was a great drop in the infant mortality; when the war was over and the factories opened there was a corresponding rise in the infant mortality. In general terms it might be said that the mortality among mothers' children was less than 10 per cent., while among wet nursed children it was a little higher; among orphans brought up on the bottle there were twice as many fatalities as there were among the wet nursed. It had been stated that child insurance was a factor in causing infant mortality, but careful investigation had excluded this. The mortality among insured children was less than the general mortality. Infanticide had been rapidly decreasing for the past ten years. The infant mortality for the registration area for 1906 was 20 per cent. of the total mortality instead of 12½ per cent., which was thought to be normal. Since 1900 the number of cases of typhoid fever had declined and also malarial fever and influenza. Measles and scarlet fever had remained the same, whooping cough and diphtheria had decreased, pulmonary tuberculosis had fallen off somewhat but not as rapidly as in the adult population, respiratory diseases had increased and also venereal diseases. Diseases of the kidneys and the circulatory system remained practically the same. The digestive diseases which showed no falling off during this period were due to infection by means of the food supply. He spoke of the effects of warm weather upon the food supply and of the dangers of infection through the agency of the fly. Dr. Stowell outlined the work done in Berlin, Paris, and New York for the purpose of bettering the surroundings of infants. He said that few young people, even those with families, knew how to care for their offspring and that social settlements, church clubs, and the general practitioner should endeavor to educate the mothers. Women about to become mothers should not be permitted to work in factories until they had regained perfect health. If, as Graham said, 50 per cent. of infant deaths were preventable, the physicians of the United States should be indicted for homicide in 30,000 instances annually. It was the duty of the physician to make the infant death rate go down. Babies should be nursed by their mothers, and if not should be given milk prescribed in proportion by the physician and not according to chance rules of the laity.

Mr. W. C. Phillipps called attention to the worthlessness of statistics which were brought forth regarding infant mortality. Even President Roosevelt made mistakes in his statistics. Mr. Roosevelt had recently stated that in Panama the people were so well that it justified the

belief that, instead of a place of pest and rot, it was the most healthy on the American continent. He did not state that the men sent there were in the prime of health and all over twenty years of age. In getting the statistics regarding infant mortality it should be asked what condition the babies were in when brought to Randall's Island and how long they stayed there. These were, in his opinion, very important questions to be asked. Women had asked him why it was necessary for them to nurse their babies when they could obtain milk already prepared and in bottles. The milk stations gave out many hundreds of bottles of milk daily and this proved one of two things, either the mothers were unable to nurse their babies, or else they were prevented from doing so because of economic reasons. Mr. Phillipps said that the high infant mortality was due to four or five principal causes: (1) hereditary weakness, (2) poverty, (3) industrial conditions, (4) impure milk, and (5) ignorance. All of these causes could be remedied.

Dr. Charles Herrman wondered why Mr. Phillipps had placed ignorance last among the factors causing the high death rate in infants, for he believed that it should be moved up a bit. Ignorance was the one factor to deal with immediately. There was no doubt but that a large part of infant mortality was due to improperly prepared food and improper hygiene. Much good had been done by the dispensaries, milk depots, lectures given by those connected with the Department of Health, etc., in properly instructing the mothers regarding the care of the baby, but these mothers represented only a small percentage, and probably were not those who needed the instruction most. Such instruction should be given as soon as the baby was born. When the birth certificate was received by the Health Department, a physician or nurse should be sent to the home to instruct the mothers on the feeding and care of their babies. If it was not possible to visit all, those reported by midwives, or persons not physicians, should be selected In order to carry out the plan properly, the mothers should be visited immediately after the birth of the child.

Dr. Thomas S. Southworth said that Randall's Island hospital for infants had now emerged from the conditions which once existed there. Since the Infant Hospital had closed in 1904 there were no infants there under two years of age and no mortality on the island. It had been repeatedly claimed of late, both at home and abroad, that the mortality in the Infant Hospital was reduced from 49 per cent. to 19 per cent. by pasteurization of the milk. Sterilization of the milk had been practised for many years before Dr. Neff established in 1896 a milk laboratory for modifying and pasteurizing the infant's milk. Two years later, in April, 1898, private philanthropy installed a very complete apparatus for modifying milk. From the increased facilities for modifying milk they hoped for better results in feeding. Pasteurization and sterilization having been previously tested without noticeable results they had, in 1898, secured sixteen to twenty quarts daily of percentage cream, enough to make all the feedings required in the hospital. This milk, then as now, required no pasteurization to kill the tubercle bacilli, as the milk was obtained from tuberculin tested cattle. The reports of the Visiting Committee of the State Charities Association in 1897 had stated that the "babies in the Infant Hospital were suffering and dying by reason of carelessness, ignorance, and inefficiency on the part of those in charge." "Nursing had shown lack of strong, steady supervision." There was then overcrowding, bad nursing, indifferent feeding, and, as a result, always a mortality. In 1898 a competent supervising nurse was appointed. New plumbing, new floors, and new ceilings were put in throughout the building. The number of wet nurses was quadrupled. Children with contagious diseases were transferred to other institutions. More children were boarded out. Overcrowding of the wards ceased. The report of the same committee for 1898 said, "the sickening odor formerly characteristic of the wards has disappeared." "Making every deduction for altered circumstances there remained a notable decrease in mortality which could only be accounted for by better food, better nursing, better care, and better administration in the Infant Hospital." No mention was here made of pasteurization as the sole cause of the reduction of the mortality, and now that Dr. Stowell had made public the facts, this claim should cease.

Election of Officers.—*Chairman*, Dr. Eli Long; *Secretary*, Dr. William Shannon.

EAST SIDE PHYSICIANS' ASSOCIATION OF NEW YORK.

Stated Meeting Held December 18, 1908.

Dr. H. Illoway in the Chair.

Indications for Hysteroctomy.—Dr. A. Brothers presented a number of specimens of uteri which he said he had chosen from some 150 or more removed by him in his service at the Post-Graduate and Beth Israel Hospitals, to illustrate the variety of conditions for which the operation was done. He presented some very large fibroid uteri, and especially one complicated with a four months' pregnancy, as illustrations of colossal tumors, removed by the abdominal route. He preferred the abdominal to the vaginal route, as the cervix could be left intact in most cases of fibroid uteri, the largest kind of tumors could be handled with comparative ease, the rest of the abdomen could be readily explored, and the operative risks were no greater than by the vaginal route. The indications for hysterectomy were usually the large fibroid tumors, cancer, suppurative adnexal disease, infected uteri, pregnancy associated with uterine neoplasms, and rupture of the uterus.

Dr. S. Epstein presented the following cases: (1) Pott's disease in an adult. (2) Pott's disease in a young man of 20, complicated with tuberculous wrist and lymph nodes, and an apical lesion. He had been operated on, and was gaining in weight. (3) Arthritis deformans of the spine, in a boy of 16.

Free Suppurative Peritonitis; Comment on Recent Discussions.—Dr. A. E. Isaacs read this paper. (See page 306.)

Dr. A. G Gerster said that Dr. Isaacs had adopted a certain nomenclature which was rough and ready. All the nomenclature which had been proposed heretofore for defining different degrees of peritonitis were purely arbitrary and were not based on data sufficiently definite. It should not be forgotten that diffuse spreading peritonitis might be a very simple condition when seen by the surgeon in its very beginnings. Every peritonitis that was due to infection of the general cavity might be called spreading and free. Dr. Gerster believed that the application of the procedure which had been proposed by Murphy to all cases did not always bring about the results claimed for it Usually no difficulty was encountered by any experienced surgeon in securing drainage in any posture. Fowler's posture was not a necessity at all. With various forms of drainage brilliant results had been gotten by all before the so-called Murphy treatment was heard of. The cases in which good advice was needed were not the cases which had been operated on within 40 hours; most of the cases at the hospital included those from the tenement portion of the city, which had been lasting for 5, 6 or 8 days, and which were really diffuse. The mortality had been very great in those cases, and they were the cases which the surgeons would like to learn how to cure. As to the factors used for classification of the cases, Dr. Isaacs had mentioned that one of the safest and best factors was the amount of area involved, but he did not believe that

this was a sufficiently strong and valid factor upon which to base a definite classification. Another factor was the quantity of exudate, and even where it was large and indicated an extensive or a general peritonitis, it did not, in itself, even then mean that the patient was in any very great danger. The quality of the exudate was another of the factors that had been brought forward. It had been said that if the exudate was slightly turbid it was sterile or harmless, and if it was creamy it contained bacilli. This again was wrong, as there were thick, creamy exudates which contained no bacilli at all, and were not virulent, while innocent-looking turbid exudates might be very septic. He thought it easy enough for any experienced surgeon to make the diagnosis of peritonitis. But all the various symptoms and manifestations had to be taken into consideration to appreciate the gravity of any particular case. An opinion based on any one symptom was unreliable and did not permit of a correct prognosis being made. When it came to the classification of results based on the variations in the cases, there it was seen that the personal equation of the observer played a great rôle. Some would define any free infection, so long as it was not confined by adhesions, as a diffuse general peritonitis. These were the men who have reported 2 and 3 per cent. mortality in their cases. Others, again, regarded as subjects of general peritonitis only such patients as were practically dead, and, as Dr. Isaacs had stated, the exact diagnosis could never be made by the surgeon. At times the incision would show exudate in the pelvis and the peritoneum injected everywhere. Surgeons were inclined to consider such a case one of diffuse general peritonitis. The patient, after being drained, immediately began to improve, and it was thought that the operation had done it; yet patients who had not been operated upon at all had improved for other reasons. Some that set in with enormous virulence might be better in two or three days. It was seen that, with defervescence of the process, localization had taken place and residual abscesses formed in various situations. From this he would conclude that all the criteria which we possessed for making a scientific classification of these diffuse peritonitides were extremely unreliable, even though they were carried on with great care on the part of the surgeon. Another point which had been brought out by Dr. Isaacs was the curious fact that in certain cases of peritonitis—fortunately in the vast majority—a tendency was shown very early to form adhesions, while in the minority this process failed It would not be the pathological anatomist nor the surgeon who would solve this enigma of peritonitis. In certain cases adhesions would form promptly, and in others not at all, while between these two extremes there would be any number of gradations. It seemed that there were conditions of economy—chemical or physiological—that determined the efficiency of this process, and this was the line of investigation now being followed up. There must be some reason why adhesions formed in some cases and not in others, and why they would at times be firm and wall off an abscess, whereas in other cases they were soft and easily broken down, and in others again did not exist at all. Among other factors incident to the gravity of the condition, there was the quantity of the infectious material which continued to be thrown into the peritoneal cavity which very naturally influenced the effect. Then, again, there was the condition of the intestinal contents. In stomach perforation, when that viscus was full, after digestion had started, the danger of peritonitis was far greater. Gravity also depended on the portion of the intestinal canal where perforation had taken place. In general as long as our knowledge of this question remained as fragmentary as it was, the statistics did not amount to very much, especially in relation to our capacity to save the patients. As to treatment, he said that the treatment as defined by Dr. Isaacs was the one followed in Mt. Sinai Hospital, and the results had improved. That had been due not only to the fact that operation had been more prompt, but also because interference with the peritoneum had been less than in former days. The intraabdominal pressure of the intestines, as brought out by Dr. Isaacs, which forced out the exudate and the irregularities of the folds and attachments of the mesentery which guided the spread of the infection, played a very important part, and were among the most important factors in the course of the disease.

Dr. H. Lilienthal said that septic peritonitis meant that we had to deal with a living poison-producing agent in the individual—not omitting to consider individual idiosyncrasy, as each one of us had his individual personal power of resistance to toxins. For instance, he knew of a family in which the slightest abrasion of the skin in any member of the family, and in some collateral branches, was followed by suppuration; they were a susceptible family. He was perfectly convinced that if a member of this family should suffer from peritonitis, it would be one of such grave sepsis that an operation would be of no use. Just as individuals had a susceptibility to pain, so they had a susceptibility to sepsis. It was something that was in the blood or somewhere in the nervous organization. He had also noticed that when one operated in cases of peritonitis, a certain number of patients were saved, while if one operated on a person who had no peritonitis and gave him peritonitis he would die. As to adhesions, there were certain classes of cases in which peritonitis was always free—as, for instance, in typhoid fever there are no adhesions. The inverted or Trendelenburg position was a method which used to be employed, the idea being that the stomata of the diaphragmatic peritoneum would absorb the exudate for elimination by the kidneys. But it was wrong, and the same principle of gravity was applied, as in the Fowler position, to assist nature to carry the septic fluid to the pelvis where it would be but slowly absorbed.

Dr. J. Wiener said that he had never been able to see the advantage, either to the patient or to the surgeon, of classification of peritonitis, for, as Dr. Gerster had remarked, the different grades were almost infinite in number. He thought a great deal of time and thought had been wasted, and a great deal of confusion had arisen by trying to classify the different grades. The old statistics of ten or twelve years ago had been improved by working along the lines of short incision, absence of irrigation, and absence of large drainage. Still, some of our German colleagues were still using these measures and claiming good results. He thought Fowler's position deserved a great deal of credit, and should be used before as well as after operation, and that any patient with appendicitis would have his chances of recovery very much improved if he were put in the extreme Fowler position, which did everything that had been said for it. The danger of drainage tubes, mentioned by Dr. Isaacs, recalled a case He had operated at the hospital, removing a gangrenous appendix, and placing a rubber drainage tube. On the sixth day he had been hurriedly summoned to the hospital and had found that a spell of coughing had started a free hemorrhage from a large vessel eroded by pressure of the tube. The bacilli which cause the peritonitis are to be considered, as well as the amount of peritoneum involved. Perhaps improvement in treatment in the future will be along the lines of serum therapy. For the present he did not think we had the right to be as optimistic as Dr. Murphy claimed. If he saw the cases in as late a stage as we, he would not be so optimistic.

Dr. H. M. Silver said that he had never adopted the Fowler position. He had surprised his house surgeon recently by ordering a patient in the Fowler position, but

next day had changed to the belly prone position, which he felt would accomplish just as much and more than the Fowler. Drainage was just as good and the patients were much more comfortable; although for the first few hours they grumbled they afterwards would ask to be placed in that position. He ascribed success in treatment to release of tension of pus in the abdomen, to drainage, and limitation of the duration of anesthesia. He did not use drainage tubes, but rubber tissue cigarette drains, and all drains were very much smaller than formerly.

Dr. A. BROTHERS said women with pus tubes were likely to have a dribbling into the peritoneal cavity, and in his gynecological work he had noted that in these cases the process was usually localized. The spilling of a little pus during excision of a pyosalpinx did not worry him. He seldom drained, for the pus could take care of itself.

Dr. C. A. VON RAMDOHR said that his experience agreed with that of Dr. Brothers as regarded infection of the peritoneum from broken pus tubes. It was the duration of the disease and the amount of perforation that counted, and also the pulse and general appearance of the patient.

Dr. A. E. ISAACS, in closing the discussion, said that he was surprised to hear Dr. Gerster say that Dr. Murphy did not operate in cases of over 40 hours' duration, as he had been under the impression that Murphy operated in all cases that came along. In regard to the criticisms by Dr. Wiener and others of attempts at classification, on the ground that it did the patient or the surgeon no good, he said that the difference between the milder and the severer forms was so pronounced that the details of the treatment of one form need not be applicable to the other. Advance in methods of treatment was the result of observation of the work of others, and if reports of results, good or bad, were made, at least the character of the cases in question should be known. He thought each should understand the other, not that some surgeons should report 2 or 3 per cent. mortality and ascribe it to a certain mode of treatment when it was due to the character of the cases, while another just as able surgeon might report a 50 per cent. mortality in a series called by the same name, but of an entirely different character. It would do the surgeon good to know that there were mild cases that should do well, and that he had done nothing wonderful when they did get well, and it would do many patients good to be treated in accordance with the conditions found and not to be turned inside out and washed, and cauterized with peroxide, and packed full of gauze, because somebody had had a case recover in spite of such treatment. As to ability of judging, on the table, of the extent of the exudate, if the method he had described in the paper be followed, the estimate could be made—not to exactness, yet sufficiently definite for the classification that had been suggested. He was pleased there were others who did not attach importance to the Fowler position. The conditions that had been spoken by Drs. Brothers and Von Ramdohr of infection of the female pelvis by gonococcal pus were not present here. The usual result was a circumscribed pelvic infection, comparable to the circumscribed abscess which was also the usual result in appendicitis. Furthermore, pus from pyosalpinx was frequently sterile, and, therefore, followed by no reaction. As to the infective organism mentioned by Dr. Lilienthal, of those in which culture results had been recorded, more than three-quarters with a mortality of about 6 per cent. had shown the colon bacillus. The other quarter, with mortality of about 33 per cent., had been mostly streptococcal.

Officers.—The election of officers for 1909 resulted as follows: *President*, C. A. Von Ramdohr: *First Vice-President*, Charles Dow Scott: *Second Vice-President*, Max Ghertler; *Secretary*, Sigmund Epstein; *Treasurer*, I. Seth Hirsch: *Trustees*, W. M. Leszynsky, Abram Brothers and H. C. Frauenthal.

THE CLAIMS OF WATER AS A THERAPEUTIC AGENT.*

By SIMON BARUCH, M.D.,

NEW YORK.

THE addition of hydrotherapy to the curriculum of this University, together with a clinic for practical instruction in the remedial uses of water, marks an innovation which is due to a desire of the faculty to add to your equipment a powerful therapeutic agent which is either not taught at all or incorrectly taught in the text books, and for this reason has been responsible for much loss of comfort and life.

The application of remedial agents is the goal of all medical study and practice, as you will quickly realize when you enter upon your professional career. The sick man clamors for relief and restoration to health and the physician who most quickly, surely, and thoroughly responds to this urgent demand will earn the confidence of the public upon which success depends.

The instructors in Materia Medica have doubtless informed you that the pharmacopœia by no means contains all remedial agents, and that there are non-medicinal agents like water, air, diet, exercise, rest, etc., which are of equal if not greater importance in some cases, because without in any manner interfering with the living protoplasm, they serve to enhance the reparative processes in disease and to improve the patient's resisting capacity to the morbific agent.

That water stands easily foremost among these physiological remedies is evident from its achievements at the bedside and its historical record, as I shall endeavor to show.

It has been demonstrated by careful clinical observation that water judiciously applied is capable of evoking many varying and at times contradictory therapeutic effects. To those who are unfamiliar with hydrotherapy, such a claim would seem unwarranted laudation. Following the division of remedies adopted by the systematic works on Materia Medica, let us note how water would lend itself to a classification made in accordance with chief action, viz., into stimulants, depressants, or sedatives, tonics, diaphoretics, emetics, purgatives, antipyretics, antiseptics, etc.

1. Is water available as a *Stimulant?* (a) When called to a fainting person the first thought of the merest tyro in medicine even is a dash of cold water upon the face and chest of the patient. You are aware that this procedure produces a stimulating effect upon the sensory terminals in the skin, that this stimulus is transmitted to the central nervous system and reflected upon motor tracts to the organs controlled by it. The patient revives quickly under this hydrotherapeutic stimulation.

(b) Are you confronted with that most pathetic of all conditions of asthenia which at the dawn of life threatens to extinguish the feeble spark in the stillborn infant? Your instructors in midwifery have taught you to meet this apalling emergency by sprinkling cold water upon the feeble infant, to resort to artificial respiration, and if still unsuccessful to dip the infant alternately in hot and cold water. In most instances this simple procedure sets the sluggish wheels of life into motion. There is no other stimulant capable of accomplishing such a therapeutic marvel.

(c) You stand at the bedside of a typhoid fever patient and sadly note his flagging vitality eloquently proclaimed by the muttering delirium, the lusterless eye, the apathetic countenance, the galloping compressible and dicrotic pulse. Put such a patient into a cold friction bath the technique of which we shall discuss when speaking of the hydrotherapy of this disease. The sufferer emerges from such a bath a changed being; the eye has brightened, apathy has faded from the face, the pulse has resumed its tension; the whole aspect of the case has been changed by this stimulating effect of water, properly administered.

(d) When you want to remove local stasis in frostbite, does your instructor tell you to apply stimulating liniments? No, he counsels the friction with ice water, to stimulate the sluggish vessels.

2. As a *Sedative.* It would seem absurdly contradictory to claim such an effect for water after what has just been stated. And yet by changing the technique of the bath, raising its temperature to about 100° F. and prolonging it considerably, the most powerful chemical sedatives have been defeated by it. Cross the East river and visit the wards of the Manhattan State Hospital; you may there see maniacal patients under the most active motor excitement taken out of the straight jacket and placed into the hammock bath, with the result that they become calm and tractable after hyoscin, chloral, and other powerful sedatives have failed. Indeed, so positive is the sedative action of various hydrotherapeutic procedures which you may learn to apply in our clinic, that the reports from the principal insane asylums are unanimous in the declaration that hydrotherapy has practically superseded all mechanical restraints and that the body- and mind-destroying chemical sedatives may be dispensed with. Some members of this class have seen with me, in Dr. Wittson's wards in the Hood-Wright Hospital, a patient with chronic meningitis who during an exacerbation developed so violent a delirium that he could be restrained only by being strapped to the bed, and yet this patient who failed to respond to

*Introductory lecture to the course on hydrotherapy in the College of Physicians and Surgeons, Columbia University.

hyoscin and chloral and trional became calm after he was placed in a hammock bath of 100° F. in which he was kept for two hours, with the result that there was no return of the delirium, and on the following day he was reading a newspaper. If such severe and intense states of cerebral excitement may be subdued by water correctly administered, it is not unreasonable to expect similar effects in the milder forms encountered in general practice.

3. As a *Tonic* you have seen the results of my method of neurovascular training in the clinic. Gain in weight indicates the attainment of the chief effect of tonics, viz., an improvement of nutrition, and many bloodcounts and hemoglobin examinations have demonstrated that no medicinal agent excels the correct application of water in producing so called tonic effects.

4. As a *Diuretic*. I have numerous bedside notes to prove that under various hydrotherapeutic procedures the quantity of urine has increased from 50 to 200 per cent., and what is of far greater influence, on recovery of the patient the toxicity of urine has been enhanced.

I have records of a case of pneumonia in which 110 ounces were voided.

5. As a *Diaphoretic* you have observed in the clinic the powerful action of the hot bath pack, which pilocarpin or other medicinal diaphoretic cannot surpass. One cannot, however, be substituted for the other. For instance the rapid comforting effect of pilocarpin in giant edema cannot be attained by this pack, while on the other hand the action of the pack in removing faulty tissue change cannot be accomplished by medicinal diaphoretics. Each has its own sphere of action.

6. As an *Emetic* the action of tepid water is well known, but when the most irritating emetics administered in narcotized patients fail, you have in gastric lavage a procedure which will empty the stomach without irritating it and remove all poisons thoroughly.

7. As a *Purgative* the action of an enema is familiar even to the layman. While water cannot be substituted for calomel or castor oil in some cases, there are others in which its application by enteroclysis is not to be approached by purgatives, as in the summer diarrheas of children and autointoxications from the intestinal canal, in icterus, etc.

8. For the *Promotion of Metabolism* and for the elimination of retrograde products of faulty tissue change we have no medicinal agent. Rubner, Ignatowsky, and others have demonstrated by accurate laboratory experiments the increase of oxygen intake and CO_2 outgo, and of N. excretion in the urine the striking action of certain hydriatic procedures in this regard.

9. As an *Antiseptic* water has come to be substituted for the poisonous antiseptics resorted to in the Listerian days of surgery. To-day irrigation with plain boiled water is universally preferred in surgical operations. It is related of the great gynecologist Lawson Tait, of Birmingham, that his success in removing pus tubes attracted many surgeons to see his operations. One day a German surgeon visited Tait at his office to obtain a permit for his operations, asked him what antiseptics he favored. Tait replied "nothing but tap water." When the surgeon expressed his surprise and stated that despite the use of the best antiseptics he had failed to obtain the brilliant results of Tait, the latter asked to see his hands and, pointing to his unclean nails, bluntly said, "That may be the reason!"

10. As an *Antipyretic*. I have purposely left this therapeutic action of water for the last, because the average physician entertains incorrect ideas upon this subject. The cold bath is always classified in the textbooks among active antipyretics, despite the physiological fact that cold increases metabolism and therefore creates heat. We shall recur to this false conception of the action of the cold bath, which above all things I want you to avoid. The true antipyretic bath is not the cold but the tepid bath. It has been amply demonstrated again and again by Riess, Barr, myself, and others, that the temperature in typhoid fever for instance may be reduced quite as readily by the continuous bath at 90° to 95° F. as by any of the coal tar series. Last year I took occasion to show a case of typhoid fever in the service of Dr. Wittson which was going on favorably under the cold friction bath when suddenly the temperature rose to 107° F. by reason of facial erysipelas. I advised to place the patient into a continuous bath of 95° F. After an hour's sojourn in this bath the temperature fell to 101° F. and the insomnia which had not yielded to trional was overcome, so that the patient almost drowned in an unguarded moment.

This review of the therapeutic possibilities of water which may be obtained only by certain modifications in the method of applying it, goes to demonstrate how important it is that you learn these methods in order to be able to avail yourselves of this flexible agent at the bedside, and thus add to your resources for the alleviation of suffering and saving of life.

Lest I lay myself open to the charge of enthusiasm—a fault which the teacher of medicine must avoid, I would not have you lose sight of the fact that there are some powerful medicinal agents which cannot be superseded by water, *e. g.* opium, mercury, quinine, and the anesthetics. Unlike these Sampsons of Materia Medica, water is not a specific, but serves a different though not less important purpose of sustaining the struggling organism in its battle with disease and menacing death, in acute cases, and to invigorate and restore failing functions in the chronic ailments in which medicines are, alas, too often powerless.

It is this large field of therapeutic adaptation of water which has led some conscientious and many unscrupluous and ignorant men to erect the hydropathic system of practice which is still the basis of the quacks who have encroached so extensively upon the practice of the German physicians and who are lying in wait for you in this country also. If you will master the principles and practice of hydrotherapy expounded in these lectures your patients will not only be saved from these medical sharks but you will contribute to the advancement of your noble calling.

It has been unfortunately the custom of physicians to treat these empirics with disdain, and what is more inexcusable and fatal to the humane and material interests of our calling to treat water with contempt because the empirics had appropriated it as their own. I hope that you will serve as missionaries, diffusing correct ideas of Hydrotherapy among the profession, when you go forth with knowledge of its merits and its failings.

History. Let us now consider the claims of hydrotherapy from a historical standpoint. Differing from all other professions, the history of medicine is rarely taught in our medical schools, and when it is referred to at all the dates of birth and death

of the great physicians are the chief subjects. Whoever has studied the history of medicine must become conscious of the fact that while its progress has been slow and halting like that of other intellectual pursuits, until the renaissance of modern times, it has been specially inactive in the field of therapeutics. Indeed we have little to be proud of in this regard. For two thousand years physicians have been dominated by the false idea that disease must be attacked by spoliative measures. That terrible octopus, bloodletting—aided by mercurial and other depletive and spoliative measures—held potent sway over the medical mind. Occasionally, though very rarely, there appeared upon the dark horizon brilliant independent thinkers, like Asklepiades, Paulus Aeginaeta, Van Helmont, Hufeland, Magendie, and in more recent times Jacob Bigelow and Oliver Wendell Holmes, who, clearly discerning the vis medicatrix naturæ of Hippocrates, endeavored to lead the medical profession back to "Nature in Disease," which was the theme of the Harvard professor Bigelow's great but unappreciated work. As we are concerned to-day with that portion of our history which treats of the development of water as a remedial agent, these historical facts are referred to for the purpose of pointing out that nearly every physician who followed the conservative practice of Hippocrates was, like him, an earnest advocate of water, and thus to impress upon you that those brilliant men among the ancients who most nearly approached the therapeutic ideas of the present enlightened era were earnest hydrotherapists.

Passing over the biblical and legendary data usually marshalled to prove the antiquity of water in therapeutics, I shall offer only authentic records. The first treatise on water was written by Hippocrates ("De Aqua et Locis"). He laid down rules for the application of water in disease which mark him as being well informed on hydrotherapy. I regard Hippocrates as the greatest medical genius of all time, because his marvelous clinical acumen prompted him, even in those days of darkness and ignorance of anatomy or physiology, to recognize "vis medicatrix naturæ" as the true curative agency in disease. He therefore enunciated and practised in that long-distant period a principle which has survived the onslaughts of skeptics for two thousand years and which began to be accepted only when the renaissance of medicine was inaugurated by revolutionizing discoveries in physiology, chemistry, and microscopy. Bloodletting and spoliative medication which dominated the entire medical profession for two thousand years lost their influence so soon as these great discoveries illumined the dark pathways and demonstrated their destructive influence upon the organic reparative processes. Water on the contrary gained adherents under the same influences, and the more intensely the searchlight of modern science shone upon it, the more clearly have the true merits of water as a therapeutic agent become manifest.

The man whose therapeutic axiom, after desuetude of twenty centuries, is followed by every enlightened physician of this day, gave us another evidence of his clinical skill in the pithy dictum "cold water warms," *i.e.* stimulates. The enormous loss of life that may be justly traced to the long disregard of this true action of cold water cannot be computed. I shall have occasion to demonstrate to you that although it has begun to be appreciated by the best trained physicians of the present day its recognition is so far from universal that cold water is still numbered among antipyretics in all the text books, and it will be my painful but imperative duty to cite hospital records of undoubted authenticity to prove that hundreds of lives have been sacrificed during the not distant past and are sacrificed at the present time by reason of this false teaching. It pains me to confess that Hippocrates divined the real action of cold water more clearly than does the average doctor of this twentieth century. Lest I be charged with unwarranted bitterness, I refer you to the thirteenth edition of the most popular work on therapeutics (American) which is a textbook in nearly every medical college; there you will find the statement "the object of the bath is the reduction of temperature, and unless this is effected no good results."

An English text book also may be cited. In his charming lectures on the "Action of Medicines," the author says: "The cold bath is a very efficient means of reducing the temperature," and he explains that in his hospital "the cold bath is a bath of 65° F. reduced by the addition of ice to 40° or lower"! He tells the students: "Put the patient into the cold bath and leave him there for a certain length of time." He says nothing of friction which should be the chief requisite in every cold bath. You will agree that no conscious patient would allow himself to be left in a bath of 40° F.; he would escape from it as soon as he touched it.

In every text book on practice the antithermic action of very cold water in sunstroke is reiterated. When we come to discuss the hydrotherapy of this malady I shall point out the fallacy and fatality of a teaching that would make Hippocrates "turn in his grave."

The immediate followers of Hippocrates continued his mild and conservative practice, but as time obliterated the force of his living example venesection became the leading therapeutic agent. Men who were ambitious to form their own schools and become leaders of new disciples disregarded the teaching of the father of medicine and built systems of their own.

A century after the death of Hippocrates, Asclepiades of Prusa, a Greek physician, emigrated to Rome to seek fame and fortune among the world-conquering people. He was so earnest an advocate of water in health and disease that he was called Psychrolutus, and it is recorded that to his influence may be traced the origin of the bathing habits of the Romans, who, according to Pliny, were enabled to dispense with physicians for 600 years by reason of their cleanliness. Asclepiades rose rapidly because he was a man of learning and genial nature and performed many marvelous cures by mild remedies, chief of which were baths and massage. He inveighed against bloodletting and spoliative practices and followed the motto "tuto, cito, et jucunde." Among his disciples three distinguished themselves. Cornelius Celsus, who by reason of his close adherence to the teachings of Hippocrates was called "Latinorum Hippocrates" and on account of his eloquence received the pseudonym "Medicorum Cicero," prescribed water freely in many acute and chronic diseases. His social influence was even greater than his medical; he became the bosom friend of Ovid and Fabius Maximus.

Coelius Aurelianus was an eminent physician

who studied and practised hydrotherapy and invented the wet compress which is so valuable in pneumonia that I regard it as the chief remedial agent in this disease.

Antonius Musa was another worthy exemplar of his master. The historian Suetonius relates that when the Emperor Augustus was given up by the physicians of the imperial household, friends advised him to summon Musa, who had treated Horace with cold water (see sixth epistle). The doctors warned him that this cold water doctor would hasten his death—as is sometimes done nowadays also. The illustrious patient recovered and erected a statue to Musa and conferred the privilege of citizenship upon all physicians.

The prejudice against cold water which existed in the time of Augustus still lingers in the minds of the lay people and of some physicians to-day. The Nestor of American pediatrics once said in the New York Academy of Medicine that he was forced to resign from a children's hospital because he was regarded as too fond of using cold water on the children. This eminent man has happily survived with undimmed reputation and is to-day an honored member of our faculty.

Two incidents from my personal experience may serve to sustain the courage of your convictions if you are ever opposed in the prescription of the cold bath. Several years ago I was requested to take charge of a prominent family in this city. I was informed that the family was opposed to the use of cold water for which I had at that time begun to make propaganda. A year elapsed before I found it necessary to prescribe baths. One of the children fell ill with diphtheria, which I managed with the usual sustaining measures (this was before the day of antitoxin)—when one night I was hastily summoned and found the child with a temperature of 106° F. and all the other manifestations of toxic heart failure. A bath of 85° F. was ordered, and while active friction was practised the water temperature was reduced to 80° F. Not a word of protest escaped the anxious and alarmed parents while in the presence of evident danger. When they saw the child returned to bed in a greatly improved condition they expressed their delight, and after they realized that subsequent cold baths contributed materially to the child's final restoration gratitude replaced prejudice. This child lived to be again saved by the Brand bath with which Dr. Shrady treated him for typhoid fever during adolescence, with my approval.

Another incident from my experience may serve as an example. Several years ago I was summoned to a desperate case of typhoid fever under the care of Dr. Joseph Fraenkel of this city. The patient had been seen by three other consultants, all of whom, like the physicians of Augustus, opposed the cold bath and advised alcoholic stimulants and other sustaining medication on account of the patients' desperate condition. Although I had been the physician of this family for some time I had not been called for two years. When I entered the sick chamber the patient was singing deliriously and did not recognize me. All evacuations were involuntary, the temperature was 102°, the pulse was 160, feeble, and dicrotic; the whole aspect of the case pointed to early dissolution. A bath of 80° F. was ordered, and to neutralize the shock carbonic acid gas from the solution of a package of Nauheim salts was added. The pulse improved, but consciousness did not return until the fourth bath. The patient recovered. One year later passing the lady while alighting from her carriage, she accosted me with grateful appreciation of my service, saying: "I must confess that I gave you up as my family physician because I wanted to escape from cold water treatment of my nervousness. This was cured in Europe by cold water, and now you have saved my life with it."

Seven hundred years elapsed before another advocate of water appeared. Paulus Aeginaeta, accounted the most eminent physician of the seventh and eighth centuries, was a true follower of Hippocrates, whose doctrines he tried in vain to revive. He was an enthusiastic advocate of water in many diseases and discovered the great value of cold affusions in sunstroke—a treatment, by the way, the neglect of which has cost hundreds of lives in this city, as I shall show by comparing its successful use by Dr. O'Dwyer of intubation fame in St. Vincent's Hospital with the fatal procedures in other hospitals.

Again one thousand years elapsed before the appearance of Vander Heyden, who, in the seventeenth century, regarded water as a powerful remedial agent and taught its application as did Van Helmont. The former reported 366 cases of malignant dysentery cured by baths in an epidemic which decimated the population of his country.

In the latter part of the same century—1697—a book, entitled "Psychrolusia," appeared in England, written by Dr. John Floyer a learned physician of Litchfield. So convincing were his arguments and clinical data that the book passed through six editions and was translated forty years later into the German language. Coming to the notice of Friedrich Hoffman, the most renowned professor in Germany, residing in Heidelberg, this influential teacher was led by it to espouse hydrotherapy most vigorously. The first recognition of the influence of cold water upon the tone of the tissues emanated from this philosophical physician. His teachings penetrated to France and Italy.

One hundred years later the English ship surgeon, Currie, reported his marvelous cures of typhus fever, a disease that had been crippling the navy. He put the nude sailors upon the deck and had them treated by affusions from buckets of fresh sea water. Currie published his observation of the favorable results of cold water in this and other diseases, acute and chronic, and the book was translated into every modern language.

In the early part of the eighteenth century Hufeland, who was regarded as the most eminent physician of his time, although he shocked his confrères by teaching that "Nature not the doctor cures," made active and successful propaganda for baths. He offered a prize for the best essay on the action of cold water in fevers, determined by the fever thermometer which had recently been invented. Dr. Froehlich, the body physician of Emperor Francis Joseph won the prize.

We now come to an epoch-making incident in the history of hydrotherapy. Despite the earnest advocacy of water by a few of the most eminent physicians of all time, water did not attain popularity among the lay people until Priessnitz, an unlettered peasant, adopted it, and by his marvelous cures attracted distinguished people to his humble and crude water cure establishment in Graefenberg. This man was led by an accident to the adoption of water as a panacea for all ills. Two of his ribs were broken by the kick of a horse, which also pro-

duced a severe contusion. As was the custom in that day, the doctors wanted to bleed him and he protested. Discovering that when he pressed his injured side against the back of a chair he found instant relief from his sufferings he directed his wife to make a broad linen bandage, wring it out of cold water, and wrap it firmly around his chest. The relief from pain and the recovery from the injury he ascribed to the cold water bandage, and this was the origin of the Priessnitz Umschlag, by which name the cold compress is to-day known. Possessing a large fund of common sense and of executive ability Priessnitz devised various baths and douches from a mountain brook which rushed over some precipitous rocks on his farm. When his children were attacked with scarlet fever he bathed and packed them in cold water; they recovered, while the homes of his neighbors were filled with mourning under the bleeding treatment then in vogue. So extensive had become his repute in 1840 that members of the aristocracy and wealthy people from all countries flocked to partake of his black bread and sour milk and of his treatment by cold water externally and internally. The rise of empirical hydropathy is due to this remarkable man who died after amassing a great fortune and thus stimulated the cupidity of other laymen to adopt his methods. In all countries the water cure system became popular and formed the basis of successful quackery. Unfortunately the medical profession, imbued excessively with the dignity of its calling, treated the remedy with the same contempt which it meted out to the quack, until a sect of nature doctors (Naturärtze) arose which really menaced the status of the doctor to such a degree in the latter part of the last century that a commission for the revision of medical studies was appointed of which the great clinician Kussmaul was made chairman. His report depicted in plain but incisive language the sad plight of the educated medical man who was frequently displaced by the quack because he had not been trained in the use of water in disease. To his sensible presentation of the claims of water and other nonmedicinal agents for recognition in the curriculum of the universities is to be ascribed the formation of clinics and chairs for instruction of students in this branch of therapeutics in Germany.

It is my purpose to thoroughly acquaint you with hydrotherapy to the end that you may be prepared not only to counteract the encroachments of the empirics but to cure your patients *tuto, cito, et jucunde*, and to add to the sum of practical achievement of our calling in the saving of life and alleviation of suffering.

THE COAGULABILITY OF THE BLOOD IN PULMONARY TUBERCULOSIS.*

A PRELIMINARY INVESTIGATION.

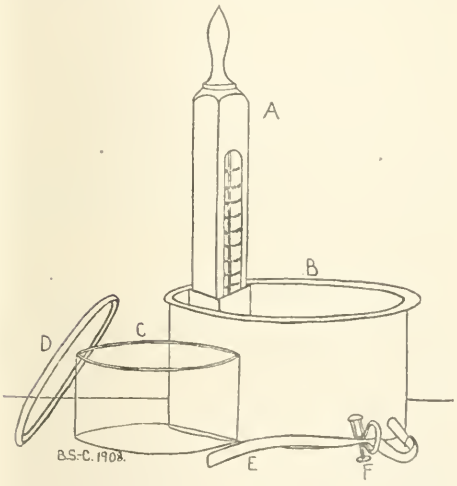
By MYER SOLIS-COHEN, A.B., M.D.,

PHILADELPHIA, PA.

CONSULTANT PHYSICIAN TO THE HOME FOR CONSUMPTIVES, CHESTNUT HILL; ASSISTANT PHYSICIAN TO THE PHILADELPHIA GENERAL HOSPITAL; CHIEF OF PEDIATRIC CLINIC, JEWISH HOSPITAL; ASSISTANT PHYSICIAN TO THE DISPENSARY OF THE HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

WITH all the attention that has been devoted in recent years to the study of tuberculosis it seems strange that no attempt has been made to investigate the coagulability of the blood in this disease. I have been able to find but two references to such a test having been made. Vierordt[1] in 1878 obtained with his method an average clotting-time of four minutes in two cases of phthisis. Several years ago using Wright's tubes I found the average time of four cases of pulmonary tuberculosis to be two minutes and a quarter.[2]

It undoubtedly would be of interest to know whether the coagulability of the blood in pulmonary tuberculosis differs from the normal and if so whether it is the same in incipient, moderately advanced, and far advanced cases. Such a study might have an important bearing upon the cause and treatment of a complicating hemorrhage, especially in view of Wright's assertion[3] that hemorrhage from the bowel and nose in typhoid fever and often hemoptysis may be associated with a serious defect of blood coagulability, and in view of the relationship between hemoptysis and hemophilia pointed out by Thompson [10] who believes that pulmonary hemorrhage is often the result of an inherited hemorrhagic tendency. The lack of definite knowledge on this



A, ordinary bath thermometer; *B*, zinc pan (common tin pan will answer); *C*, German Stender dish; *D*, lid of German Stender dish; *E*, rubber tube; *F*, clamp.

point is surprising when one contemplates the almost universal use of calcium salts in pulmonary hemorrhage. Many important questions arise in this connection. Is the clotting-time different in patients who are spitting blood from that in those who are not, and in patients who are subject to hemorrhage from that in those who have never experienced it? Does it vary with the degree or duration of the bleeding, and does it change as the hemorrhage continues? It was in an endeavor to answer these and other questions that the present investigation was undertaken.

The Method of Testing Employed.—The blood was tested according to the method devised by the writer,[4] which is a modification of Milian's method, but provides against evaporation and changes in temperature. The rim of a German stender-dish is smeared with lanolin, the lid is fastened on with a rubber band, and the inverted dish is placed in a pan of water whose temperature is maintained at 37° C. (98.6° F.) by the addition of hot and cold water. The dish is taken from the

*Read before the Section on Clinical Study and Therapy at the International Congress on Tuberculosis, Washington, D. C., Sept. 21 to Oct. 12, 1908.

water, quickly dried, and removed from the lid. On the inverted lid are deposited several drops of blood obtained without undue pressure from a deep puncture made with a sharp lance-pointed instrument, the first drop having been removed and the finger being wiped off after each drop is taken. The dish is again laid upon the lid and held in place by the rubber band. With a millimeter scale held under the inverted dish the diameter of each drop is measured, after which the dish is again placed in the water-bath with the lid underneath. At intervals the dish is removed from the pan and tilted, while the drops are inspected both from the side and from the front. On profile view the drop sags, becoming tear- or pear-shaped, before it is clotted; when coagulation is complete it does not change its shape on moving the dish but remains convex in outline. When the dish is held vertically and looked at in front, the drop will be seen to be denser below and clearer above when not coagulated, but darker in the middle or of an even density after clotting has occurred. Note is taken of the size of each drop, the moment it appears on the finger, and the time it is completely coagulated. The interval between the two records is taken as the clotting time. Drops with a diameter under 5 cm. or over 7 cm. are usually disregarded. The average time of the drops used is considered the average clotting-time.

The advantages of this method over the others are that (1) the contact surface is limited in extent, clean and uniform in character, (2) there is practically no evaporation, (3) the temperature is definite and constant, (4) the size of the drops is uniform, (5) the personal equation is largely eliminated, (6) the method is simple and easily available, (7) the results are fairly constant.

Factors Influencing Coagulation Time.—Comparative work on the coagulability of the blood is rendered difficult on account of the variations of the clotting-times obtained with the different instruments. The average normal time with the method just described is 8 2-3 minutes, with the Brodie-Russell instrument and its modifications about 5½ minutes, with Wright's tubes 2½ and 5 minutes, with Vierordt's method 9½ minutes, with Buchmaster's 5¾ minutes, with Biffi's 8½ minutes, with Bezançon and Labbé's modification of Milian's method 10 minutes, and with Hinman and Sladen's modification about 6½ minutes. Where two limits are given by writers I have taken the mean. In different hands and sometimes in the same hands the same apparatus often gives different results.

This variation is due not only to faults of technic affecting the blood after it has left the vessels, but also to other factors influencing the coagulability of the blood while still in its regular channels. As the writer has shown,[6] the latter include meteorological conditions, such as barometic pressure and humidity, viscosity, hemorrhage, meal-time, certain diseased conditions such as jaundice, typhoid fever, and urticaria, certain drugs, namely the salts of calcium and the citrates, alcohol, and blood serum. There are doubtless other sources of error which are still unrecognized.

In order to compare records taken with different instruments I have suggested the following schemes.[5] A pathological clotting-time obtained with any apparatus may be expressed as a fraction, the numerator of which is the pathological time and the denominator the normal time as given by the same method. This fraction may be expressed as a decimal or in terms of percentage. A pathological record obtained with one instrument may also be expressed in terms of another method by means of proportion, the fraction just described being made to equal a fraction whose numerator is x and whose denominator is the average normal clotting-time of the method in terms of which it is desired to express the figures.

The Coagulability in Tuberculosis.—The patients examined were in the writer's wards at the Home for Consumptives, Chestnut Hill, and in his tuberculosis class at the Medical Dispensary of the Hospital of the University of Pennsylvania, in the tuberculosis wards of Drs. Albert P. Francine, Howard S. Anders, Ward Brinton, and H. R. M. Landis at the Philadelphia General Hospital, in Dr. Solomon Solis-Cohen's and Dr. T. Mellor Tyson's wards at the Rush Hospital for Consumption and Allied Diseases, Philadelphia, and from the tuberculosis wards of Dr. Geo. F. Fetterman at the Jewish Hospital, Philadelphia. I desire here to express my thanks to these men for their courtesy in granting me the privileges of their wards.

One hundred cases were examined, 134 tests being made on them. The average coagulation-time of the 100 cases was 5 1-6 minutes, which may also be expressed as 3-5 or 60 per cent. of the normal, and was practically the same in incipient, moderately advanced, and far advanced cases (as classified by the National Association for the Study and Prevention of Tuberculosis). In afebrile cases, moreover, the time differed very little from that in cases with high fever or with moderate rise in temperature. It would seem, therefore, that blood coagulability is increased in pulmonary tuberculosis.

The clotting-time seemed to be slightly affected by some meteorological conditions, although this might have been due to accidental causes.

The outdoor temperature cannot be said to exert any influence. On days when the temperature was above 75° F. the clotting-time was 2-5 of a minute longer than on days when the thermometer registered 75° F. or less; but, on the other hand, it was very slightly shorter on days when the mercury went up to 80° and above than on days when it failed to reach this point. The time moreover was but 1-7 of a minute longer in cases examined in very hot weather than in those tested on cooler days.

Barometric pressure did not seem to be a factor in these cases, although in forty-two tests made on nontuberculous patients the clotting-time was longer on days when the barometric pressure was high.

The coagulation-time, however, did seem to be affected by the humidity, averaging 5½ minutes on days when the humidity was 70 and above and 4⅞ minutes on days when the humidity was below 70; and again 5½ minutes when the humidity was 75 and below, and 5 minutes when the humidity was below 75. This is likewise slightly at variance with my records in nontuberculous cases.[5]

Sunshine also seemed to exert some influence. On days favored with more than eleven hours of sunshine the clotting-time averaged but 4 9-10 minutes, while on days with eleven hours of sunshine or less the average time was 5 5-9 minutes.

The cases of pulmonary hemorrhage are too few in number to permit the drawing of definite conclusions. It would seem, however, that persons with increased coagulability are less liable to hemorrhage than those whose coagulability is deficient. The clotting-time was 4 5-7 minutes in patients

who had never had hemorrhage, 5 5-9 minutes in those who had spit blood within two days, 6 1-3 minutes in persons who had experienced hemoptysis within a week but who were free from it when examined, and 5 3-5 minutes in those who had suffered from hemorrhage at some time but not within two weeks.

Only three cases were examined, both before and during a hemorrhage. In them the clotting-time was 7 1-8 minutes before the bleeding and 4 minutes while it was in progress. This is in accordance with the general observation that hemorrhage is followed by increased coagulability as noted by Hinman and Sladen[6] in typhoid fever, and by Robertson, Illman and Duncan[7] in typhoid fever, abortion, carcinoma of the uterus, and hemorrhage after venesection. Vierordt[1] attributes this increased coagulability to absorption of tissue juices into the depleted vessels.

There also seemed to be some relation between the character and course of the hemorrhage and the coagulation time. The bleeding was less severe and diminished more rapidly in patients whose clotting-time was short than in those in whom it was delayed. The clotting-time was 5 3-8 minutes in those whose sputum was blood-streaked and 6 1-3 minutes in those with slight hemoptysis. Of the cases that began with severe or slight hemorrhage those that only exhibited blood-streaked sputum when examined had a clotting-time of 5 1-4 minutes while patients who were still spitting blood in larger quantity had an average time of 6 1-2 minutes.

The small number of hemorrhage cases may be due to the fact that the tests were made chiefly during July and August, as blood-spitting seems to be noticeably infrequent in the summer; at least such has been my experience and that of several of my colleagues. In two of the hospitals from which I obtained my cases hemoptysis did not occur for a space of two months. A large hospital that never contained less than 200 consumptives and often experienced three and four deaths a day had only a few cases of moderate blood-spitting a week, and severe hemorrhage was quite rare. Thompson,[10] on the other hand, holds that the season at which hemoptysis is most rife is during the summer heat, and he has drawn up a table of 1,000 cases in which the date of the blood-spitting was accurately known that shows the very large preponderance of cases occurring during the summer months. Anders[8] also found that spring and summer show the highest incidence in hemoptysis, but in a recent personal communication he states that a more comprehensive study proves the reverse to be true.

In order, however, to obtain information of practical value many series of observations on patients with hemorrhage will be required. This will necessitate daily tests made before, during, and after a hemorrhage over long periods of time and in large numbers of cases, regard being had to the season and the temperature. These of course can best be undertaken by those residing in tuberculosis hospitals or sanitariums. From the knowledge thus gained it may be possible by examining the blood to tell whether a patient is likely to have a hemorrhage and so be able to take measures to prevent it.

The coagulability of the blood should also be determined separately in patients who have and in those who have not been taking calcium salts. Calcium salts should be administered to one set of patients with delayed coagulability but who are not spitting blood, and their subsequent clotting-time compared to that of another set who are given the drug. In like manner comparison should be made of the clotting-time of patients with hemorrhage who are taking calcium and of those who are not. In this way definite information will be gained as to the action of this drug in preventing or checking pulmonary hemorrhage.

It is not uncommon for female consumptives to spit blood at the menstrual period. The clotting-time in the few cases I examined was practically the same in all instances of hemoptysis in women whether or not they were menstruating or were at the menstrual period. There can be little doubt that hemoptysis in women is often a vicarious menstruation. The possibility of such an occurrence should naturally have an important bearing at times upon prognosis and treatment. A comparative study of the clotting-time of healthy and tuberculous women both during and between their menstrual periods could not fail to prove of value.

Wright[9] applies the term "serous hemorrhage" to increased transudation of plasma through the capillary wall as seen in pleural effusion, serous diarrhea, etc., and suggests the existence in these cases of a connection with deficient coagulability. As pleural effusion and serous diarrhea both occur as complications in tuberculosis I included them in this investigation. In one case of pleural effusion the clotting-time was over 10⅛ minutes, in one case of hydropneumothrax 4½ minutes, in one case of empyema 3½ minutes, and in one case of pyopneumothrax 3⅜ minutes. The cases are too few to admit of any conclusions. It would seem, however, that coagulability is diminished in simple effusion but increased when pus is present in the pleura.

Eleven of the patients who had diarrhea gave an average clotting-time of 5½ minutes, not much longer than that of cases without diarrhea. No questions were asked, however, as to the character of the diarrhea. But even if regarded as a "serous hemorrhage" the question suggests itself: Would not the loss of fluid in a serous diarrhea have a tendency to increase the viscosity of the blood and at the same time its coagulability?

The coagulability of the blood in tuberculosis offers a large field for study. No one realizes more than the writer the inconclusive character of this investigation due to the paucity of cases. Enough, nevertheless, has been shown to demonstrate that the coagulability of the blood in pulmonary tuberculosis offers a large field for study with some probability of obtaining information of practical value. It is to be hoped that those who have the facilities will undertake the lines of inquiry suggested. With the stender-dish method the worker will at least have the satisfaction of knowing that the results of his labors will not be vitiated by faults of technique.

Below are given the figures in detail, including the maximum and minimum as well as the average clotting-times obtained and the number of cases and tests on which each record is based.

THE CLOTTING TIME IN PULMONARY TUBERCULOSIS AND IN ITS VARIOUS STAGES.

Classification	Number of		Clotting Time in Minutes		
	Cases	Tests	Average	Longest	Shortest
All stages.	100	134	5 1-6	10 3-8	2 1-8
Incipient	26	32	5 1-7	8 1-2	2 1-8
Moderately advanced	27	32	5 1-7	8 1-2	2 1-2
Far advanced	47	70	5 1-5	10 3-8	2 5-8

CASES DIVIDED ACCORDING TO THEIR TEMPERATURE.

Classification	Number of Cases	Number of Tests	Clotting-time in Minutes Average	Longest	Shortest
Afebrile	5	5	5 1/4	7 1/2	2 1/8
98.7° to 100°	36	48	5 1/9	10 3/8	2 1/2
Above 100°	36	49	5	9 1/8	3
Temp. not recorded	27	32	6	10 3/8	2 1/4

CASES DIVIDED ACCORDING TO THE OUTDOOR TEMPERATURE ON THE DAY OF THE TEST.

Classification	Number of Cases	Number of Tests	Clotting-time in Minutes Average	Longest	Shortest
80° and above	55	72	5 1/7	10 3/8	2 1/4
Below 80°	45	57	5 1/4	10 3/8	2 1/8
Above 75°	81	99	5 2/5	10 3/8	2 1/4
75° and below	19	28	5	7 7/8	2 1/8

CASES DIVIDED ACCORDING TO THE BAROMETRIC PRESSURE ON THE DAY OF THE TEST.

Classification	Number of Cases	Number of Tests	Clotting-time in Minutes Average	Longest	Shortest
30.10 and above	41	52	5 1/5	10 3/8	2 1/8
Below 30.10	56	74	5 1/5	10 3/8	2 1/4

CASES DIVIDED ACCORDING TO THE HUMIDITY ON THE DAY OF THE TEST.

Classification	Number of Cases	Number of Tests	Clotting-time in Minutes Average	Longest	Shortest
70 and above	55	71	5 1/2	10 3/8	2 1/4
Below 70	41	55	4 7/8	10 3/8	2 1/8

CASES DIVIDED ACCORDING TO THE HOURS OF SUNSHINE ON THE DAY OF THE TEST.

Classification	Number of Cases	Number of Tests	Clotting-time in Minutes Average	Longest	Shortest
11 hours or less	45	52	5 5/9	10 3/8	2 1/8
More than 11 hours	52	72	4 9/10	7 3/4	2 1/4

THE CLOTTING-TIME IN PATIENTS WHO HAVE SPIT BLOOD WITHIN TWO DAYS; CASES DIVIDED ACCORDING TO THE SEVERITY OF THE HEMORRHAGE.

Classification	Number of Cases	Number of Tests	Clotting-time in Minutes Average	Longest	Shortest
All hemoptysis	27	34	5 5/9	8 1/2	2 1/4
Severe hemorrhage	6	7	5 1/3	7 5/8	2 1/4
Slight hemorrhage	6	7	6 1/3	8 1/2	2 7/8
Streaks of blood	15	20	5 3/8	7 3/4	3 5/8

HEMORRHAGE WITHIN TWO DAYS; CASES DIVIDED ACCORDING TO THE DAY OF THE HEMORRHAGE ON WHICH THE TEST WAS MADE.

Classification	Day of Hemorrhage	Number of Cases	Number of Tests	Clotting-time in Minutes Average	Longest	Shortest
Severe and light	1st	6	7	6	8 1/2	3 3/8
" " "	2d	2	2	6 1/8	7 3/8	4 7/8
" " "	3d	13	1	2 1/4	2 1/4	2 1/4
" " "	4th	0	.....	.....	.....	.....
" " "	5th and after	4	5	5 5/8	8	3 3/8
Streaked	1st	3	5	6	7 3/4	3 7/8
"	2d	5	5	5 1/2	7 3/8	4
"	3d	2	2	5 3/4	6	5 1/2
"	4th	1	2	3 3/8	3 5/8	3 3/8
"	5th and after	3	4	5 3/4	7 3/8	4 1/4

HEMORRHAGES THAT WERE SEVERE OR SLIGHT AT FIRST DIVIDED ACCORDING TO WHETHER THEY WERE THE SAME WHEN THE TEST WAS MADE OR WHETHER THEY HAD DIMINISHED TO STREAKS.

Condition at Time of Test	Number of Cases	Number of Tests	Clotting-time in Minutes Average	Longest	Shorest
Severe or slight	4	7	6 1/2	8	3 3/8
Streaked sputum	6	6	5 1/4	7 3/8	2 1/2

RECORDS ON THE SAME PATIENT TAKEN BOTH BEFORE AND DURING A HEMORRHAGE.

Day before Hemorrhage	Clotting-time	Day of Hemorrhage	Clotting time
5	7 1/2	5	5 3/4
38	7 1/2	3	2 1/4
36	6 1/2	1/2	3 7/8

HEMORRHAGE WITHIN SEVEN DAYS OF TEST BUT WHICH HAD CEASED WHEN TEST WAS MADE.

Classification	Number of Cases	Number of Tests	Clotting-time in Minutes Average	Highest	Lowest
All kinds	6	8	6 1/3	10 3/8	3 5/8
Severe	2	3	5 3/4	7 1/8	4 1/2
Slight	3	3	7 1/2	10 3/8	5 1/4
Streaked	1	2	3 5/8	3 5/8	3 5/8

NO HEMORRHAGE WITHIN TWO WEEKS; CASES DIVIDED INTO THOSE THAT HAVE NEVER HAD AND THOSE THAT HAVE HAD HEMORRHAGE.

Classification	Number of Cases	Number of Tests	Clotting-time in Minutes Average	Highest	Lowest
Never had hemorrhage	28	38	4 5/7	8 5/8	2 3/8
Had hemorrhage	34	40	5 3/5	10 3/4	3 1/8

HEMORRHAGES IN WOMEN IN RELATION TO THE MENSTRUAL PERIOD.

Classification	Number of Cases	Number of Tests	Clotting-time in Minutes Average	Highest	Lowest
Menstruating	4	5	5 3/4	6	4 7/8
At menstrual period	2	2	5 3/4	6 1/4	5 1/4
Neither of above	10	16	5 2/3	10 3/8	3 3/8

CASES OF DIARRHEA.

Number of Cases	Number of Tests	Clotting-time in Minutes Average	Highest	Lowest
11	13	5 1/2	10 1/8	3 3/4

Visceral Rheumatism in Children.—E. Weill and Lucien Thevenot describe a form of rheumatism which affects the heart without any involvement of the joints or joint pains. Its appearance is insidious, and endocardial and pericardial lesions are progressive. There are pulmonary symptoms. The evolution of the disease is often fatal, death occurring with a syndrome that indicates parenchymatous myocarditis. The post-mortem lesions show the endocardium, pericardium, and myocardium affected as well as the pulmonary tissues. Treatment is unsatisfactory.—*Archives de Médecine Infantile.*

THE TREATMENT OF PATIENTS WITH HEMIPLEGIA RESULTING FROM CEREBRAL APOPLEXY.*

By WILLIAM M. LESZYNSKY, M.D.,

NEW YORK.

NEUROLOGIST TO THE LEBANON AND HARLEM HOSPITALS.

In a varied association with physicians both in hospital and consultation work, I have repeatedly observed that the unfortunate hemiplegiac, should he survive the first two weeks, does not receive the attention that his condition demands. The rational and judicious treatment of these patients is a subject which must perforce appeal to the general practitioner, who is called soon after the onset of the attack.

Cerebral apoplexy is often the first intimation of an unsuspected chronic nephritis associated with arteriosclerosis. Not infrequently, it happens that the individual is apparently in good health and attending to his customary duties when unexpectedly stricken. I can readily recall many cases of this nature, and the same is no doubt a common experience.

Hemiplegia, which occurs suddenly or rapidly, is essentially due to arterial disease. In the majority of cases the vascular degeneration is found in conjunction with chronic nephritis or syphilis. Hemiplegia may also result from other causes, such as embolic softening, meningeal hemorrhage, tumor formation involving the motor tract, a unilateral lesion in the upper cervical region of the spinal cord, or cranial traumatism. Cerebral hemiplegia arising in a person under 35 years of age, excluding the causes just mentioned, is usually suggestive of syphilis, *i.e.* either obliterative endarteritis, gummatous infiltration, or direct pressure.

It is beyond the scope and time limit of this paper to enter into a dissertation on the etiology and symptomatology of cerebral apoplexy in its various phases. My remarks will therefore be confined to a general description of the hemiplegic condition in the adult as a result of cerebral hemorrhage, incidentally referring to arterial thrombosis and embolism.

Hemorrhage may arise in any part of the brain, but it occurs more commonly in or near one of the corpora striata, as the lenticulostriate arteries are the vessels, par excellence, in which miliary aneurisms develop through degeneration of their muscular coats.

Thus, from a combination of pressure upon and destruction of nerve fibers, the conduction of motor impulses through the internal capsule is suddenly interrupted. The consequent hemiplegia is never so complete as to present a maximum loss of power. Not infrequently the face escapes entirely. The extremities affected are always on the side opposite the lesion in the brain. This depends upon the anatomical fact so well known to you all, that the motor tracts decussate in the medulla. The face is paralyzed in its lower portion, on the same side as the hemiplegia, as the fibers from the facial center pass down into the internal capsule and cross over to the opposite facial nucleus. Therefore, any unilateral lesion in the brain, situated above the decussation, if it causes paralysis at all, invariably produces paralysis of the opposite side. When the right side is affected, it is commonly associated with some form of aphasia, on account of the implication of the fiber tracts from the speech center in the left hemisphere.

In exceptionally rare instances there has been found congenital absence of the pyramidal decussation. The hemiplegia then occurs on the same side as the cerebral lesion. Such an anomaly does not require serious consideration under the circumstances. It must always be borne in mind, however, when cerebral surgery is contemplated.

Hemiplegia from arterial thrombosis is, in my experience, quite as frequent as that due to hemorrhage, but thrombotic softening is at times of more serious import. Cerebral hemorrhage usually occurs suddenly without prodromal symptoms, and often terminates life abruptly, or within a few hours or days. On the other hand, thrombosis is almost invariably preceded by premonitory signs such as headache, vertigo, tinnitus, numbness in the hand or foot, transient facial paresis or aphasia, or transient hemiparesis. It may also end fatally in a few days. Most of the symptoms heretofore described by numerous writers, and transmitted to posterity from textbook to textbook, as preliminary to cerebral hemorrhage, are in reality the accompaniment of endarteritis which produces narrowing of the lumen of cerebral vessels, thus interfering from time to time with the circulation, and ultimately terminating in complete and permanent occlusion and circumscribed cerebral softening. The extent of the brain lesion depends on the location and size of the vessels involved. Among the exciting causes precipitating an attack of cerebral hemorrhage through suddenly increased arterial tension, are excessive emotions, a cold bath, temporary obstruction to the return circulation from the brain in such actions as violent coughing, sneezing, immoderate laughter, or straining at stool. Several instances have ocurred in my experience, and no doubt many of you have heard of or seen similar cases, in which the patient has been found in the toilet either paralyzed or dead from cerebral hemorrhage, undoubtedly as a result of straining at stool. Cerebral hemorrhage sometimes occurs while the individual is making some vigorous muscular effort, or otherwise subjecting his vascular system to an excess of pressure. Or sudden exposure to cold air may increase the blood pressure by inducing extensive contraction of the cutaneous vessels.

When apoplexy occurs suddenly without loss of consciousness, the paralysis is evident. During coma, however, the diagnosis is frequently attended with difficulty, owing to the general and complete muscular relaxation. The stertorous breathing and the associated facial paralysis are often quite characteristic. Should consciousness be lost suddenly and profound coma with several general convulsions rapidly supervene, immediately followed by muscular rigidity, there is in all probability an extensive hemorrhage into the ventricles. All of these symptoms are directly due to the resulting excessive intracerebral pressure. When the patient is found comatose, and apoplexy is suspected, the following observations will prove useful in determining the presence of a unilateral brain lesion, for, as a rule, the hemorrhage is limited to one hemisphere: (*a*) If careful watch is kept, one may note an occasional movement of a limb on one side, while there is complete absence of any movement on the opposite side. (*b*) There may be conjugate deviation of the head and eyes toward one side, thus indicating that the lesion is on the side of the

*Read before the East Side Physicians' Association, January, 1909.

brain toward which the eyes are turned. (*c*) The presence of a unilateral Babinski plantar reflex; or the Gordon reflex, which is produced by lateral pressure on the calf muscles, both being manifested by dorsal flection of the great toe, and demonstrating involvement of their corresponding pyramidal tract. (*d*) Hughlings Jackson's sign. In quiet respiration, the movement of the paralyzed side of the chest may be greater than that of the opposite side, while in voluntary respiration, the side on which paralysis is present moves less than the other side. The latter part of this valuable observation can be utilized to advantage only after coma has subsided. If the coma is only partial, and the muscular resistance is feeble or lost upon one side, the diagnosis is evident.

While the patient remains unconscious, the prognosis as to life is doubtful, as we are unable to determine the extent of the hemorrhage. Death usually results if the coma continues more than 24 hours. Or, later, a fatal termination may take place from hypostatic pneumonia, pulmonary oedema or asthenia.

A comprehensive knowledge of general medicine and a familiarity with the pathology of this affection, constitute a sine qua non in its management. Should the patient be seen shortly after the onset of the attack, let him remain, if possible, at the same place, or limit his movements in transportation as much as possible, avoiding all jarring of the head and body, and everything tending to emotional excitement. If conscious, he must not assist in any way. He should be placed in bed, the clothing carefully removed, and the head and chest raised. To relieve stertor, turn the body on the paralyzed side and gently draw the tongue forward. If possible, a positive diagnosis should be made before instituting energetic treatment. Venesection is indicated only when the presence of cerebral hemorrhage is practically certain, and when there is congestion of the face and head, and unusually high blood pressure, with a strong, full pulse. A small, weak, frequent pulse and pale face is a contraindication. The withdrawal of about ten to twelve ounces of blood is usually sufficient. It is preferable to operate on the non-paralyzed side. In such cases, venesection is of great value in reducing the excessive blood pressure, but only at the very beginning of the attack. It is often followed by transient improvement. The stupor diminishes, the respiration is less labored, and the pupillary reaction returns. Several cases have been reported in which it was followed by surprisingly good and permanent results. In severe cases, however, it is rarely successful, although temporary improvement may occur. In my experience, a repetition of the bleeding is useless. A man fifty years of age, with cerebral hemorrhage and profound coma, when seen two hours after the onset, the systolic blood pressure was over 300. The removal of 14 ounces of blood reduced the pressure to 190. He then became conscious and spoke rationally to his family, but in a few hours he gradually relapsed into coma with a blood pressure of 320. This was again reduced by venesection, but the coma persisted and he died on the third day.

As an exact differentiation between apoplexy from hemorrhage and that from thrombosis or embolism is often impossible, venesection should never be practised in doubtful cases. In thrombotic softening it is not only useless but harmful. The arterial pressure may also be lowered, more slowly, of course, by the administration of tincture of aconite, two or three drops every half hour until effectual. Or, a ligature about the extremities close to the trunk may prove serviceable in diminishing the volume of blood in the internal organs, thus relieving the intravascular pressure and hastening the formation of the clot. This procedure is most likely to prove efficacious when the symptoms are indicative of a large hemorrhage, or in those cases in which there is an apparent tendency to an extension of the hemorrhage. It must be borne in mind, however, that in old people a somewhat high blood pressure is a normal condition. During the attack of cerebral hemorrhage the rise in blood pressure is assumed to be due to irritation of the vasomotor centers in the medulla, and may be considered, in a measure, conservative. Hence, the blood pressure must not be reduced too low. If coma lasts more than a few hours, the bladder should be emptied by catheter. When there is reason to believe that there is an accumulation of feces and the blood pressure is high, two drops of croton oil or one quarter of a grain of elaterium may be placed on the tongue; or, if the patient can swallow, give one fluid drachm of saturated solution of sulphate of magnesia every two hours; or an enema if required. Always satisfy yourself by personal investigation as to whether the patient is able to swallow, and do not depend upon the statement of the nurse or attendant, for there is danger of producing a fatal aspiration pneumonia. Even if the patient is able to swallow, do not force food upon him. Ordinarily, he may with safety do without food for 24 to 48 hours. If necessary, food may be administered per rectum, and medicine either per rectum or subcutaneously. When there is great restlessness or delirium, or convulsions, chloral or hyoscine hydrobromate may be used. In alcoholists small doses of whiskey or brandy may be required. In mild cases, too much active treatment may prove harmful. Either the hemorrhage is so large that it is beyond the influence of treatment, or it is so small as to require no special measure. The presence or absence of chronic nephritis must always be taken into serious consideration.

When the apoplexy and paralysis are due to arterial thrombosis, it is associated with low blood pressure. Hence, the special plan of treatment is just the opposite to that for cerebral hemorrhage, although rest in bed and the same general management are essential. The blood pressure may be increased by saline rectal irrigation or hypodermoclysis, and the administration of caffeine, strychnine, or tincture of strophanthus.

A similar plan may be followed when the thrombotic softening is the result of an embolus, although other indications must be met in relation to the associated cardiac affection.

If syphilis is known to be the cause of the arterial disease, iodide of potassium or sodium should be given in doses of about five grains every three hours, in addition to mercurial inunction.

Nephritic patients may become hemiplegic during a uremic attack, as a result of vascular spasm or localized cerebral edema, the so-called uremic hemiplegia. Should this be accompanied by semi coma and convulsive seizures, it may often be materially alleviated by the withdrawal of 50 to 75 cc. of cerebrospinal fluid by lumbar puncture.

Bedsores over the sacrum and over the heels are not essential features of the malady, but are usually the result of carelessness and neglect. The position

of the patient must be frequently changed, and, either by a water-bed or by various mechanical devices, the points that are subjected to pressure must be protected. In rare cases the formation over the buttocks of a so-called bedsore, which is due to trophic changes, may occur despite the most careful vigilance.

Should consciousness be restored, and the vitality be maintained, the prognosis as to recovery from the paralysis depends upon a number of factors. The bloodclot, in interfering with the innervation through the pyramidal tract, may produce a complete hemiplegia, partly from pressure upon and partly from destruction of nerve fibers. The period of inflammatory reaction varies from ten days to two months. The fibres that are torn across never regenerate. Pressure upon others gradually subsides during the absorption of the clot, and their normal function is resumed. This most frequently occurs in the fibers going to the lower extremity. In many cases of hemorrhage spontaneous improvement may therefore be expected. On the other hand, in softening due to embolism or thrombosis, less improvement will follow, as a collateral circulation is never established when the area of softening is large enough to produce a complete hemiplegia lasting for several days.

The hemiplegia is always of the same general character, whether the cerebral lesion be due to hemorrhage, thrombosis, or embolism.

There is neither clinical nor experimental evidence to prove that we possess any drugs whose administration will hasten the absorption of the extravasated blood, or help to establish a collateral circulation in an area of softening, and thus relieve the patient of the immediate cause of his paralysis.

Recovery from hemiplegia will occur from any kind of lesion, if it be a small one. If the patient begins to move the arm the next day, he is likely to get well altogether. We cannot infer so much from early recovery of the leg, as this is very often not completely paralyzed at the outset, and we know that it frequently recovers when the arm remains paralyzed. It happens not infrequently that in mild cases of cerebral hemorrhage associated with hemiplegia, that the leg recovers within a few hours. When the patient is seen later, it may be incorrectly assumed that we are probably dealing with a cortical or subcortical lesion limited to the centers or fibers for the arm and face. The history of the onset and early progress will clear up any doubts. In such cases, there is a small hemorrhage either in the internal capsule or the corona radiata.

Before the patient is able to leave the bed, which is usually at the end of two or three weeks in favorable cases, much can be done by careful management and close attention to details to prevent unnecessary complications.

Furthermore, we must constantly bear in mind that central nerve fibers that have been torn across or broken up in any part of their course do not undergo regeneration, and that motility can not be restored in those parts which receive no motor impulses. We must not delude ourselves in the belief that we can cure the hemiplegia. As previously mentioned, a partial restoration of function usually takes place spontaneously, and need not be attributed to the treatment.

In this connection it will be of interest to call your attention to some of the clinical signs of the cerebral type of hemiplegia which are not usually observed nor their value recognized. Corresponding to the well-known fact that in the facial paralysis accompanying hemiplegia the orbital portion of the nerve is usually unaffected, a similar phenomenon may be observed in the upper extremity in the fibers of the spinal accessory nerve. This nerve divides into two branches—one supplying the sterno-cleido-mastoid muscle, and the other, the upper segment of the trapezius. As a rule, the branch to the sterno-cleido-mastoid escapes, while that supplying the trapezius is paralyzed. The latter paralysis manifests itself in the drooping of the shoulder while at rest. The paralysis in the lower extremity, which is usually neither complete nor permanent, also shows several characteristic peculiarities, which explains the fact that walking is still possible even in severe cases. In such patients, while in the supine position, one can demonstrate that active elevation of the extended leg to a certain height can still be accomplished, although feebly.

Dorsal flexion of the ankle joint is nearly or completely abolished, but plantar flexion can be performed with considerable force. In the prone position, the flexors of the knee joint are nearly or completely paralyzed, while the extensors show a well-marked or almost normal strength. Therefore, in hemiplegia the muscles which are especially important in locomotion are the ones that are the least affected.

While Nature aids us materially in the absorption of the clot, we must aid Nature in the care of the paralyzed limbs, which, if left to themselves, frequently undergo changes that will render them more or less useless. This is especially so in the upper extremity.

In the paralyzed arm, the shoulder joint being relaxed, arthritis is prone to develop and terminate in ankylosis, unless suitable measures are adopted. From the very beginning, the arm should be supported in a sling in order to prevent traction on the ligaments, and the shoulder joint be subjected to gentle passive movements several times daily. At the end of a week or ten days, the entire extremity should receive daily massage and pasive motion of all joints, the patient gradually being taught to make efforts at voluntary movement. The lower extremity should receive similar treatment. In this way, much can be accomplished toward preventing such an unnecessary complication and consequent increase of the disability. Neglect of this important precaution invariably results in the formation of adhesions and a stiff shoulder joint. In order to be efficient, this plan must be followed intelligently, systematically, and persistently.

Electricity, in the form of Faradism, should not be used until about four weeks after the onset of the attack, the strength of the current applied to the paralyzed muscles being just sufficient to produce slight but evident contractions. The applications are to be made every alternate day, the entire seance lasting from ten to fifteen minutes. Faradization keeps up the nutrition of the paralyzed muscles and improves the peripheral circulation. The same may also be accomplished by massage and volitional movements when possible. In view of the fact that the extensors in the upper extremity and the flexors in the lower extremity are the muscles usually paralyzed, our electrical and manual manipulations should be directed in greater part to these groups of muscles.

There is no proof that strychnine, glycerophosphates, or other so-called "nerve remedies" directly

influence the paralysis. Their use should be restricted to those cases in which they are indicated for improving the general health.

Rigidity of the limbs may be present at the very beginning of the attack, indicating excessive cerebral irritation or ventricular hemorrhage. When rigidity of the paralyzed limbs takes place as a late manifestation (*i.e.* several months later) and is accompanied by exaggerated knee-jerk, ankle clonus, and the Babinski plantar reflex on the paralyzed side, no further recovery need be expected, as secondary degeneration of the motor tract has taken place.

The treatment of the aphasic state associated with hemiplegia requires special educational methods.

Later, our efforts must be concentrated with a view to the prevention of another attack. This constitutes a prominent feature in the management at this stage. The first attack may prove conservative, inasmuch as it may lead the patient to follow instructions faithfully and thus prolong life.

It may now be asked upon what grounds are we enabled to infer a predisposition to cerebral hemorrhage, and what means are to be adopted for its prevention? (Some families exhibit such a predisposition, but this is usually an indirect result of the inherited tendency to arterial degeneration.) 1. From the history of a previous attack. 2. From the constitutional state which induces arterial degeneration, *i.e.* senility, chronic nephritis, rheumatism, gout, diabetes, syphilis, lead poisoning, etc. 3. From the presence of arterial degeneration itself, as manifested in the radial and temporal arteries by their rigidity and tortuosity. This evidence of arteriosclerosis is extremely suggestive, but is not positive proof of a similar condition of the cerebral vessels. It has recently been claimed that tortuosity and prominence of the temporal arteries are commonly due to the frequent pressure of a rigid hat band. As a matter of fact, however, many cases are on record in which post-mortem examination and careful microscopical investigation have shown normal cerebral vessels coexisting with degenerated temporal and radial arteries. The presence of retinal hemorrhages and ophthalmoscopic evidence of arteriosclerosis furnish indications of considerable value. They are extremely significant, inasmuch as they point to a state in which cerebral hemorrhage is most likely to occur. 4. From the presence of continuous high blood pressure (as determined by the radial pulse and the sphygmomanometer), chronic interstitial nephritis, and ventricular hypertrophy.

These are matters which demand painstaking investigation. In all cases of cerebral apoplexy, and in those patients with a manifest tendency thereto, the condition of the arterial system is a factor of cardinal importance. Too much emphasis can not be laid upon this point.

For several years I have used the Riva Rocci sphygmomanometer in estimating the systolic blood pressure. While the results of such examinations are not absolutely accurate, they are approximately correct, and clinically very valuable, being far more reliable in experienced hands than the customary tests of the pulse tension with the fingers. In the early stage of cerebral apoplexy it has proved a source of great satisfaction to me as an invaluable aid in differential diagnosis between hemorrhage and thrombosis, and thus indicating the most suitable plan of treatment. It is a useful adjunct during venesection.

We should never fail repeatedly to examine the urine, and satisfy ourselves as to the integrity of the heart and kidneys. In fact, every organ in the body should be examined.

Granting that the arterial degeneration is to a great extent irremediable, let us devote our attention to the regulation of the blood pressure and the avoidance of exciting causes of the arterial rupture.

Every patient should be impressed with the possible danger to which he is exposed while straining at stool, and be instructed to avoid conditions likely to produce sudden increase of arterial tension. In conjunction with the foregoing, the general plan which will be found appropriate in most cases is to regulate the diet, to diminish the amount of nitrogenous food, to keep the bowels free, to avoid excessive water drinking where there is high blood pressure, and to reduce high blood pressure by the use of salines or mercurials, nitroglycerine, the nitrites, aconite, or thyroid extract, and to give antisyphilitic remedies when necessary.

I have thus endeavored to briefly outline the proper plan to be adopted in the management of an unfortunate class of patients who tax our resources to the utmost. Much of our success in averting another attack will depend upon the intelligent cooperation, self-denial, and self-control of the patient.

616 Madison Avenue.

TUBERCULOSIS OF THE BREAST.*

By EUGENE ST. JACQUES, B.A., M.D.,

MONTREAL, CANADA.

ADJUNCT-PROFESSOR OF CLINICAL SURGERY, LAVAL UNIVERSITY.

The intention of the paper is not to review the whole question, but simply to call the attention of the members of this association to certain aspects of the affection, clinical as well as therapeutical.

Tuberculosis of the mammæ is a rather rare affection. If we have noted it perhaps more frequently since some 25 years or so, it is because the attention of clinicians as well as pathologists has been drawn to certain inflammatory conditions of the breast, indolent in their evolution and particularly slow at healing.

Sir Astley Cooper in England, Velpeau in France, and Foerster in Germany seem to have been the first to signal out tuberculosis of the breast. But their affirmation was not sufficient in the eyes of the exclusive pathologists. Virchow, in his "Lehrbuch der Geschwulste," and Cornil and Ranvier, in the first edition of their "Manuel d'Histologie Pathologique," without refusing to admit the theoretical possibility of tuberculosis mammæ, said that there were no definite and true cases known. But here again clinical studies had preceded the microscope. Let us recognize that since that epoch, the latter has gradually come more and more to the front and that now-a-days both the clinician and the pathologist work harmoniously hand in hand.

Anyhow, opinions were unsettled on this point until Dubar in a thesis, proposed before the Paris Faculty in 1881, clearly proved tuberculosis of the breast to be a well defined pathological entity. Among the cases which have come under my observation, I shall briefly summarize the clinical his-

*Read before the Canadian Medical Association, at its annual meeting in Ottawa, 1908.

tory of two, which will serve as a basis for the conclusions I desire to propose.

Case I.—Miss H., 16 years old, comes to my clinic on account of trouble in the left breast which presented a small abscess on the point of bursting, altogether superficial, on the outer side of the nipple. It had grown gradually without causing any pain whatever. Some five cubic centimeters of pus were drawn from it. The microscopical examination revealed neither Koch bacilli nor streptococci nor staphylococci. On the same breast were two cicatrices of previous abscesses, which had similarly begun by a nodule, enlarging gradually and later on softening into a small pus collection, which had opened by itself, all this time causing no pain whatever. On the right breast was an old cicatrix, and presently an ulcerated surface as large as a five-cent piece. Both were weeks and weeks before healing and scarcely had the one on the left breast healed when a new one formed near the nipple and like its sister abscesses was particularly slow at healing. The general state of health was always excellent. To-day, two years later, the young lady, particularly well developed for her age, is in excellent health. The cicatrices show well but are not adherent to the gland, save the one in the neighborhood of the nipple, which has been drawn in.*

Case II.—Miss C., 20 years old, came to me in 1906 on account of an ulceration in her right breast, cough, and lately hemoptysis. Some weeks previously a nodule appeared which grew larger, then softened, and finally without having caused pain an abscess opened spontaneously. Microscopical examination of the secretion from the ulcerated surface showed strepticocci and staphylococci. The ulcer was many weeks before healing. A year later later she came back having had one attack of slight hemoptysis. Presently, anemia appeared and signs of infiltration in the left subclavicular region. Since then the patient has been lost sight of.†

Are these two cases typical ones? Of course objection can come from the fact that the Koch bacillus was not found. Let us first see if such is usually the case. What we can gather from the published clinical observations on the subject leads us to a negative conclusion. Reverdin reports that von Bruns found the bacillus in two cases; but it is impossible to trace up these observations. Anyhow in these two cases of mine, the clinical history is typical of the disease. Both were young girls, perfect personal cleanliness, no anterior infection save tuberculosis, concomitant tuberculosis of the lung in one of them, the painless evolution of the affection, the absolutely torpid character of these ulcerations, their aspect, their long time in healing; all lead to the conclusion of tuberculosis mammæ.

Let us see if tuberculosis of the breast is exclusively met with in women? No. There are cases, very few indeed, of tuberculosis mammæ in man. Such for example was a case of Mayor, reported by Poirier (in *Archives générales de médecine*, 1882) and a case reported by Delbet (in "Traité de chirurgie," Duplay at Reclus, I edit, vol. V).

As for the age, we can infer from the cases reported, that this affection is unknown before puberty, that it is very rare after fifty, that its greater frequency is between the ages of 20 and 30.

And how does the bacillus tuberculosis gain entrance to the breast? In three different ways: (1) By way of the nipple and its lactiferous ducts, as Verneuil claims; (2) by way of the lymphatics and then again secondarily to a neighboring lesion of the pleura, ribs, or glands; finally (3) by way of the blood-vessels, as Orthmann pretends. All of which goes to say that tuberculosis mammæ may be primary or secondary.

Out of 26 cases analysed, the mammary or corresponding axillary lesion was the sole one in 12 cases; 10 had simultaneously pulmonary lesions, and 4 other tuberculous lesions. In two of my cases there were pulmonary complications.

And now what about local predisposing causes?—that means inquiring if anterior mastitis or a trauma may bring about a local development of tuberculosis. A traumatism, affecting a patient already tuberculous, might be an exciting cause; but if the wounded is not already tuberculous, it seems to be without any effect. As for mastitis, let us remark that such a coincidence has often been noted, but at the same time I must insist on the fact that tuberculosis mammæ seems more frequent in unmarried young women.

Should we now look into the clinical aspects of this affection, we would infer the following conclusions from the cases which have come under our observation and those reported. Tuberculosis mammæ presents itself under one of these three aspects. In the first case the tuberculous foci are localized under the skin and very superficially. The nodules are generally indolent and painless, and, as they enlarge, usually soften. Soon a fluctuating area makes itself evident. If such purulent collection is not properly attended to, the skin soon becomes reddish and thin and the abscess bursts spontaneously. Such was the case with a patient of Poirier, one of Orthmann, and one of Kramer.

Now again—and these are the most frequent cases met with—the tuberculous foci are deep seated and it is only by chance that the patient discovers one or more nodules in the breast. The following is a typical case of this class: Miss C., 28 years old, came to me on account of a mass noticed in her right breast. Painless at the beginning, it had gradually grown to be, if not painful, at least troublesome. On examination I found a nodule about the size of the yelk of an egg and hard. Toward the axilla two other nodules, small and hard, which had been noticed only lately. Nothing in the armpit. Temperature, 99.2°. Pulse, 80 to 85. The patient is anemic and pale and has lost flesh lately. An incipient costosternal periostitis is present on the right side. There is an infiltration at the apices of both lungs. These nodules gradually evolve toward abscess formation in one focus, or secondary nodules appear, each giving rise to as many so-called cold abscesses, which may coalesce into one large cavity or develop independently.

Then again in a third variety of cases, the bacillus is localized primarily in the neighboring glands—axillary or more generally pectoral. This tuberculous adenitis may exist for a long time, even years, before involvement of the mamma.

It is in this category of lymphoglandular origin that I would place three other young patients who came under my care: Eva P., 17 (1905); Albina F., 29 (1907); Cleo L., 13 (1907), all single, who had developed primary pectoral adenitis, one of

*Four months later the patient presented a deep-seated nodule in the right breast, giving rise to no pain. Her general state of health was excellent.

†The patient has been seen lately, since the above was written; she is in excellent health. The breast is definitely healed and cured.

them showing later on a secondary polyadenitis of the axilla; and these glands were tuberculous. The first patient, who then showed signs of incipient tuberculosis of the lung, is now, as reported by her attending physician, in an excellent state of health and is apparently cured of her pectoral fistulæ which were a very long time at healing. Excision and cauterization were done in all of these cases.

As for treatment, three ways of dealing are at our disposal: (1) To treat these cold abscesses of the breast as we do those of similar nature elsewhere, that is: evacuating by aspiration, with the strictest of aspetic precautions, and then injecting into the pouch a modifying liquid, either iodoform-glycerin or ether, or one of Calot's mixtures, viz., iodoform and creosote with ether and oil; (2) to open, cauterize, and drain; (3) or else again—and this a more radical treatment—to excise the whole of the breast and clean out the axilla. Da Costa and Keen, Kümmel and von Bergmann, von Bruns, Delbet, all advise excision *in toto,* claiming from experience far better results through this radical procedure. Nevertheless we hesitate to accept such a radical suggestion for all cases. For there are cases in which the patient comes to us with only small abscesses, as well localized as superficial, subcutaneous ones, without the least glandular reaction, where to excise at once the whole organ seems to us a rather hasty procedure.

I now close this paper with this proposition: If excision of the breast and cleansing of the axilla is the treatment of choice in a large number of cases of tuberculosis of the breast, there are also cases with superficial and subcutaneous localization but no lymphatic reaction, in which evacuation by aspiration and injection of a modifying fluid, or else cauterization with the thermocautery, ought to be used, before making the more radical operation of excision of the breast.

ACHYLIA GASTRICA VERSUS INSUFFICIENTIA PYLORI.

By MARK I. KNAPP, M.D.,
NEW YORK.

We have here to consider whether achylia gastrica is a disease, whether it exists at all, or whether the clinical picture represented by achylia gastrica should be recognized as insufficiency of the pylorus. In accordance with my researches, now supported by other evidence, the medical profession should drop the term achylia and substitute for it insufficientia pylori. As in medicine generally, so here also, the name is more than a mere denomination. I ask for this change because the term achylia not only confuses as to the actual underlying cause, but because it implies facts and conditions of the stomach which do not exist. Einhorn defines achylia as "the absolute cessation of all gastric secretion," a definition which not only is not warranted but is grossly misleading. For, with the condition of the absence of all gastric functions in our mind any therapy becomes a sort of placebo and the patient is permitted to drift along as best he can, and he usually drifts from bad to worse. If, however, the profession accept my teaching that the identical clinical picture which is taught as being achylia is in reality due to insufficiency of the pylorus, then an excellent prognosis is offered in lieu of the gloomy outlook achylia implies. The practitioner is offered this selection: Achylia, with the uncertain and rather bad prognosis or insufficientia pylori which is not only of excellent prognosis but is capable of speedy improvement, manifestations of improvement appearing often within 48 hours. It is, therefore, not an academic question to substitute insufficientia pylori for achylia gastrica, but it is of the utmost necessity to recognize the true condition. My statements are very bold, indeed, but true. Especially in diseases of the gastrointestinal canal the true diagnosis is of so much importance. It is one thing to assume the existence of an atrophy of the mucosa and it is quite another to be absolutely certain that such an assumption is chimerical and founded on insufficient investigation. True, atrophy of the gastric mucosa exists, but the clinical picture we are called upon to interpret as due to atrophy is not so caused. Naturally, we treat according to the diagnosis made. Fallacious diagnosis, fallacious treatment. When by reason of the diagnosis of achylia gastrica we assume a desiccation, as it were, of the gastric mucosa the line of treatment will of necessity differ from the treatment we must adopt when we know that the cause of the trouble is altogether something else. Insufficiency of the pylorus

means that for some reason or another the pylorus cannot close tightly, as it normally should, and because of such inability the food passes on into the intestines sooner than it should. Quite often, in old protracted cases, the food seems to drop right into the intestines without remaining in the stomach for any time at all. Such conditions prevailing, it is self-evident that no food can be aspirated at the usual time of one hour after the test breakfast, or only a trace of food according to the degree of the relaxation of the pylorus. In order to explain this absence of food and the slightly acid, or more often, the alkaline or neutral reaction, the teaching of achylia gastrica assumes the operation and coexistence of two contradictory, diametrically opposed conditions. The absence of food is explained as due to hyperkinesis of the muscularis, and the absence of gastric digestion is ascribed to the atrophic condition of the mucosa. The fact that the stomachs of the so-called achylics very seldom show any organic changes does not bother the believers in achylia gastrica. There is no food in the stomach—cause, the working overtime of the muscularis; there is no acidity in the stomach—cause, atrophic condition. Could we not lead this thought to some more logical conclusion and argue: One has a hemorrhage—cause, there is too much blood; one has chills—cause, he ate too much ice cream? How simple medicine would become. Achylia gastrica forces us to recognize the synchronous presence of hypermotility, which is an excessive physiological action with atrophy, which means no physiological action at all. Could we only induce the stomach of the patient to become atrophic, just to oblige us and to justify our diagnosis, we might stretch a point just for the sake of good comradeship, as to the real existence of hypermotility. But the trouble is, the stomach is obdurate and fails to be won over, and persists in remaining absolutely normal in almost every case. Of course, achylia teaches that the hypermotility of the muscularis is only to compensate for the atrophy of the mucosa, a sort of *manus manum lavat;* on the principle "one good turn deserves another."

When in 1902 (*Philadelphia Medical Journal,* May 24, 1902) I described for the first time insufficientia pylori as a sequela of chronic gastritis I assumed the presence of this condition from the facts that presented themselves, and which I had learned to diagnose as achylia. At that time I had no anatomical evidence to prove the correctness of my contention. I argued that if the selfsame stomach which showed absence of food and digestion acidities one day, an hour after the test breakfast, did show perfectly normal conditions the following day when, instead of waiting with the aspiration one full hour I only waited half the time, I could hardly admit the existence of an atrophic condition of the mucosa, I could not help concluding that the supposed atrophy was imagination. The next thing I had to do was to find an explanation for the absence of food at a later time. This is the conclusion I reached.

Anatomically, the pylorus is the lowest part of the stomach when the person is either standing or sitting. Hence all food and drink, following the natural laws of gravity, fall to the lowest level, to the pylorus. Normally, the pylorus closes on the introduction of food or drink into the stomach and opens at certain intervals. During these intervals portions of food are projected into the duodenum. It is necessary that the physician fully understand this mechanism. Neither the closing nor the opening is effected by any other agency or influence than the normal peristalsis. Active peristalsis closes, passive peristalsis, the relaxation, the recoil after the contraction, opens the pylorus. Inasmuch as to open denotes an active condition, and the opening of the pylorus is not due to active participation in the work by the muscularis, we really are not entitled to say that the pylorus opens, but rather that the pylorus relaxes. I have already explained in former articles why and how peristalsis closes the pylorus, and will here repeat that the peristaltic wave, striking the narrow pylorus, causes the muscularis of the pylorus to contract just as it does that of the body of the stomach. The selfsame amplitude of contraction which diminishes the diameter of the stomach cavity diminishes also the diameter of the pylorus. But, owing to the fact that the diameter of the pylorus is only a small fraction of that of the body of the stomach, and that the lumen of the pylorus is only about a quarter of an inch wide, but little contraction is sufficient to close it entirely. If, for some reason or other, the pylorus is incapable of contraction, if it remains open, any food or drink taken into the stomach will escape into the intestines because of mere gravity. Now the question is: is there such a thing as the incapability of the pylorus to contract? This question is answered in the affirmative in my first article. (Lest I be misunderstood, I refer to the insufficiency of the pylorus as a sequel of chronic pyloritis. I have cited Ebstein's case of insufficiency and also the insufficiency assumed to be caused by some nervous derangement.) The premises I started from were the assumption that at some previous time there was an overactivity of the pylorus, an overcontraction, which means that at some previous time the pylorus, excited too strongly, responded with either too violent or too prolonged contraction; hence a too violent or a too prolonged occlusion of the pylorus. For the time being such occlusion acts and has the effect of a stenosis, and I termed it "stenosis pylori ab irritatione." Such a stenotic condition may, and very often does, occur in the very first days of our lives, produced either by improper feeding or by improper food. Undoubtedly such a stenosis in such early days will produce a coalescence of the mucous membranes of the opposing surfaces and the stenosis becomes real, organic, fatal. How many of the so-called congenital stenoses really have such an origin is hard to maintain; but unquestionably a great many belong in this class. The oft repeated and prolonged irritation of the gastric mucosa causes oft repeated and prolonged stenosis of the pylorus. The consequence of this is the gradual weakening of the muscle of the pylorus, analogous to the weakening of the muscles in any other part of the body following overexertion. The pylorus tires from overactivity, if I may use such a phrase. The passing of a previous stenosis into a subsequent insufficiency is well known to medicine. So that, if a preexisting stenosis can be proved the assumption of the succeeding insufficiency follows as a matter of course. There is no doubt now as to the existence of a benign stenosis of the pylorus, more correctly to be called 'stenosis pylori ab irritatione." Clinically, the stenosis is evidenced by pain or even cramps in the region of the pylorus and the trained hand will feel the contracted pylorus; the examination of the test meal yields a large quantity of chyme which separates on standing into two layers: a very fine, "floury" lay-

er at the bottom and a thin fluid over it. As soon as the pylorus begins to weaken the just mentioned symptoms show gradual abatement. The pain is lessened, smaller quantities are aspirated, and the aspirated chyme becomes less floury and more coarse, its appearance becomes "spongy." The once stenotic pylorus may finally become so insufficient that the stomach can hold nothing at all. The transition from stenosis to complete insufficiency is usually very gradual; gradually the pylorus weakens more and more. When, one hour after the test meal has been eaten, the aspiration yields only one or two c.c. of a coarse chyme, usually imbedded in mucus, the diagnosis of insufficiency of the pylorus is justified. The degree of the insufficiency must be ascertained by repeated test-meal examinations on succeeding days. Every day we shorten the time of waiting for the aspiration by 15 minutes. So that the first day we wait one hour, the following day only three-quarters of an hour, then only half an hour, then 15 minutes. If this last examination is unsuccessful, the patient is put on his back for 15 minutes after the test meal the following day and, if this test prove again unsuccessful, the patient is given a coffee test meal the next day and again one waits only 15 minutes. This coffee test meal consists of 200 c.c. (not 300 c.c., as in the usual test meal) of black coffee and 35 grams of roll. If there is any contractility left the black coffee will excite it. This is now my routine method. The black coffee test meal is my last resort. The knowledge arrived at by these repeated test meals is very important not only for prognosis but especially for treatment. As the treatment is alkaline we must be sure of the degree of the insufficiency so that we do not give the alkalies too soon after eating, thus destroying whatever stomach digestion there may be left. If, on the other hand, we give the alkalies late enough, we permit a certain amount of the ingested matter to pass into the intestine where a certain amount of decomposition takes place before the alkalies have reached it. The alkalies must be given at a time when the stomach is ascertained to be empty.

If the stomach of the selfsame patient shows one day the clinical picture of achylia and the following day yields a good quantity of chyme and digestion acidities (when the aspiration is performed half an hour earlier than the day before) the condition of atrophy of the mucosa of the stomach can never be assumed. How can the stomach be atrophic one day and be perfectly normal the succeeding day? If there is atrophy of the mucosa, that atrophy is there whether we aspirate one hour after eating or whether we aspirate 15 minutes after eating. True, Einhorn speaks of some cases that showed achylia for some years and then bestirred themselves and apparently regenerated the mucosa of their stomachs, which then showed good digestion. But, at least years are made to elapse between the atrophy and the regeneration. Or have the stomachs of my patients, just for my delectation, played hide and seek with me, now I digest and now I don't? If there were atrophy the day before, whence came the good gastric secretion the day following? To be sure, I had not decided the question whether this was insufficiency or achylia until I had made sufficient examinations on a number of patients.

The fact that I could aspirate some contents if the patient lay on his left side, when there had been no contents the day before when the patient was in the usual sitting posture, shows that the posture had a decided influence. One, surely, would not dare assert that the "hypermotility" which is made to explain the absence of the chyme in the stomach operated only in certain positions of the body. My intention in changing the position of the body is to change the lowest point of the stomach. In the sitting and standing posture the pylorus is the lowest, but when one lies on his left side the lowest point of the stomach is shifted to the fundus. Therefore the ingesta gravitate to the fundus in the last mentioned position, but they do gravitate past an open pylorus in the normal sitting or standing position. We have in this change of position a positive proof of the operation of the purely physical principle of gravitation in an open pylorus. This fact must be impressed on the physicians that the mere change in the posture produces a vital change in the gastric manifestations. Sitting or standing, the picture of achylia, lying down, and there is evidence of digestion. It is hardly conceivable that the gastric mucosa, atrophic in one position of the body, magically regains the lost glands if the posture of the patient be changed.

The proper recognition of insufficientia pylori, as a true and an existing condition—not as an occasional nervous phenomenon—does not involve solely a question of diagnosis; it involves more, it involves the question of whether or not the patient is to be cured. With the diagnosis of achylia gastrica we grope around in the dark and try to catch at anything in the vain hope of doing something good. In insufficientia pylori the road is not only definitely marked out, but it leads to absolute and speedy cure.

As stated before, I arrived at the conclusion regarding the existence of insufficientia pylori after uninterrupted failures in my attempts to cure the patients of achylia. It was then that I decided to explore the condition of the stomach more thoroughly and at a time less than one hour after the eating of the test meal. Rather, it was curiosity, experimentation, without any idea of what I might find. Only after I had obtained good chyme half an hour after the eating of the test meal, while the day before the same patient gave the unequivocal picture of achylia gastrica, and after I had obtained the same results in many other cases, was it that I rejected achylia gastrica with all its teaching. Achylia gastrica does not exist although there are isolated and rare cases of atrophy of the gastric mucosa. Insufficientia pylori is mistaken for any of the grave chronic diseases—tuberculosis, heart disease, diabetes, cancer, etc. Imagine the case of a patient presumed to be affected with any of these diseases of unfavorable prognosis being not only benefited, but actually cured in a few weeks, and this, irrespective of how long the suffering had continued. The almost instant and favorable response to the proper treatment of insufficientia pylori is little short of the miraculous; the nagging and gnawing symptoms of many years' standing show marked abatement often in less than 48 hours; this without the use of any of the narcotics or other pain-quieting remedies.

The illogical acceptation of the coexistence of atrophy and hypertrophy of the same organ at the same time should not be tolerated in medicine. The picture of achylia presents apparent absence of gastric secretion and absence of chyme. The first is explained as caused by atrophy of the mucosa and the latter as produced by an overaction, overmotility of the muscularis. The coexistence of such con-

trary conditions is assumed not because of any positive proof, but because of the inability to account for the symptoms in any other way. That the numerous operations speak against such theories, that the many autopsies do not prove the existence of any atrophy, is not taken into consideration.

Insufficientia pylori has had to stand the test of time. Even if there appeared isolated supporters of my teaching the whole question was a matter of inference until the appearance of Moullin's article ("Pyloric Stenosis and the Conditions of the Pylorus During Life," *Lancet*, January 19, 1907). Moullin tells us that he has made it a practice to examine the condition of the pylorus whenever the opportunity presented itself during laparotomies. He writes: 'For some time past, whenever I had occasion to open the abdomen for the purpose of operating upon the stomach, I have made it a practice to examine the pylorus as thoroughly as I could . . . the pylorus . . . while it was fixed with the left hand the index finger of the right hand was made to invaginate the wall of the stomach some way off and was pressed against, or where it was possible without using undue force, pushed into the pylorus . . . In those cases in which the stomach was opened the examination was afterward completed with the finger in the interior. . . . From the interior of the stomach the pylorus feels like a round opening with well defined edges which just admit the tip of the forefinger. . . . I found that the size of the pylorus varied from that of a channel which could easily admit three fingers with the invaginated wall of the stomach around them to that of a tiny orifice which could scarcely be felt. The former was in a patient who was suffering from general enteroptosis . . . the pylorus was so indefinite that it was difficult to find, the sphincter could scarcely be felt, and the stomach and intestines seemed to form one continuous canal without a break." It seems to me that these notes on the finding of actual conditions remove once and for all any doubts as to the existence of the disease as described by me five years before the appearance of Moullin's article. Insufficientia pylori is no more a hypothesis but an actuality, an absolutely existing condition. Boardman Reed has this to say in his book on "Diseases of the Stomach and Intestine," page 868: "When pyloric incontinence exists in the absence of any mechanical cause for it, the more plausible explanation seems to be the one championed by Knapp, viz., that the muscle has become exhausted by long overaction." That we may not be misled by thinking that under complete anesthesia there must be also a relaxation of the sphincter we have this from Moullin: "Tonic contraction . . . which does not entirely disappear from involuntary muscles, even when the reflexes are abolished." Also, Moullin found the pylorus in every degree of contraction under the identical conditions of complete general anesthesia. Hence general anesthesia does not cause a relaxation of the pyloric sphincter.

The remarks here made are intended not only to establish the existence of the disease, insufficientia pylori, as I originally described it, but also to prove the fallacy of achylia gastrica. Let the reader bear in mind the extreme importance of the diagnosis of insufficientia pylori. Let the reader bear in mind that insufficientia pylori may masquerade as tuberculosis, as a cancer hidden somewhere, as neurasthenia, etc. Let the reader bear in mind that the diagnosis of a fatal disease invariably leads to a fatal prognosis and that this again, most likely, to a fatal issue because of improper medication. Let the reader bear in mind that insufficientia pylori is the natural sequel of chronic pyloritis (incorrectly and commonly known as chronic gastritis). Let the reader bear in mind that, as such natural sequel, insufficientia pylori is one of the most common diseases. Let the reader bear in mind that no matter how long the patients suffered—and I have had patients who suffered for over 40 years—the patients do get well and are completely cured under the appropriate treatment for insufficientia pylori in an almost miraculously short time. Let the reader bear in mind that achylia gastrica has been born of an insufficient conception. Let the reader bear in mind that there is no such thing as achylia gastrica

616 Madison Avenue.

Bradycardia in Appendicitis in Children.—The Budapest correspondent of the *Lancet* draws attention to the importance of bradycardia in children suffering from appendicitis. This symptom has not been dealt with as yet; in the literature of the subject there is only one memoir referring to bradycardia in appendicitis, and in it only adults are considered. Professor Bókay draws the following conclusions from an experience of ten cases treated successfully. 1. During the absorption of the periappendicular exudation bradycardia sets in almost regularly and persists for many days; it may even last for more than a fortnight. 2. Bradycardia may also be observed after an appendicular abscess has been evacuated by an operation. 3. In children between the ages of seven and 16 years the pulse rate ranged from 52 to 80. 4. There is no parallelism whatever between the pulse-rate and the temperature. 5. Bradycardia cannot be regarded as an unfavorable sign from the point of view of prognosis; on the contrary, in cases of periappendicular exudation it is a sign of the commencement of the process of absorption. In all the ten cases observed by Professor Bókay the bradycardia must have been of extracardia, *i.e.*, nervous, origin, because organic heart disease could be excluded. He was therefore justified in assuming that the essential cause was irritation of the vagus, probably due to the absorption of toxins from the periappendicular exudation.—*The Lancet.*

A Series of Thirteen Pylorectomies.—G. Faysse describes a series of thirteen pylorectomies performed by him recently. He gives histories of these cases, and follows them by his conclusions as to the value of the operation. It is not always possible in appropriate cases to find a distinct tumor in the stomach or intestine. Absence of vomiting does not assure us of permeability of the pylorus. In all cases at the age of fifty, without past digestive troubles, with loss of flesh and gastric pain an exploratory laparotomy is justifiable. The chemical history of the gastric juice cannot be relied upon for diagnosis. The mobility of the pylorus is the criterion as to appropriateness for operation. If it is movable resection is in order. Any serious adhesion to the pancreas contraindicates it. The enlargement of the lymphatics may be purely inflammatory. Out of thirteen operations the microscopic examination showed ten to be malignant growths; three were benign. There was always thickening of the walls, ulceration of the stomach mucous membrane, and absence of this in the duodenum. Three patients died: one after a long and difficult operation and prolonged anesthesia; one operated on too late and in bad general condition; one of purulent pleurisy. Five of those who survived operation are dead from recurrence of the growth. Five are still alive.—*Archives Provinciales de Chirurgie.*

The Ganglionic Nervous System of the Human Uterus.—M. Kieffer has made an examination of the nervous system of an infant two months old as to the ganglions of the uterus and vagina, thus confirming the observations made by him on the uterus of the dog some years ago. He finds in the walls of the uterus and vagina a chain of ganglia of the sympathetic comparable to the other ganglia of the sympathetic system. These ganglia are well defined and he has been able to demonstrate multipolar cells in the ganglia. He has not demonstrated single isolated cells or masses of cells as were seen in the dog.—*Bulletin de la Société d'Obstetrique de Paris.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, February 27, 1909.

THE PULMONARY APICES AND TUBERCULOUS INFECTION.

THE frequency with which tuberculosis of the lungs begins in the pulmonary apices has called forth numberless theories in explanation of the fact. That a general predisposition of the apical portions of the lungs to tuberculous infection exists in all individuals has been claimed by some observers, but the absence of universal tuberculous infection of the lungs disproves the correctness of this view. Other observers have searched for some slight differences between the apices of tuberculous subjects and normal individuals, and one such difference discovered many years ago by Freund consists in the presence of a partial stenosis of the upper aperture of the chest caused by abnormal shortness of the upper ribs.

Of late a number of other workers have taken up this theory and among them Carl Hart who writes on this aspect of predisposition to tuberculosis in the *Münchener medizinische Wochenschrift* for January 19, 1909. In addition to the abnormal shortness of the upper ribs Hart has found in such ribs premature ossification combined with rudimentary development, all of which lead to interference with the ventilation of the apices by the respiratory movements of the chest. These deformities lead, namely, to the formation of acute angles in the direction of the bronchi leading to the pulmonary apices and predispose likewise to stagnation of expired air in the regions of the apices; they enable thus the inspired bacilli to settle in a part of the lung tissue diminished in its natural power of defense against infection. One very strong point in favor of the truth of this theory is given by the circumstances usually attending the occurrence of tuberculosis in other portions of the lung than the apices; in such cases there is frequently the history of quite another predisposing moment, such as trauma or diabetes, which has exposed to infection an individual who otherwise would not have been attacked by the disease. Still further argument in the same direction is the well-known frequency with which tuberculosis of the lungs in infants begins in the central portions of the lungs about the hilus while the apical regions are spared. Hart correctly states that stenosis of the upper thoracic aperture does not exist in children in whom all the ribs are still growing in length; in them the infection that may have been carried to the lungs by the inspired air, by the lymph channels, or by the blood finds the most favorable site about the least expansile portions of the lung in the region of the hilus near the large bronchial glands that often serve as the primary foci of the disease. The increase in the frequency of tuberculous infection of the apices that is noticed in the fourth to sixth decade of life may be explained by the interference in the ventilation of the pulmonary apices caused this time not by abnormalities of the ribs but by the beginning senile rigidity of the chest walls that produces a like effect.

Hart's studies lead him to conclude that the prevention as well as the cure of incipient tuberculosis depends a great deal upon the realization of this congenital or acquired predisposition of the apices to the infection; whether operative interference with the upper ribs or more conservative attempts to overcome the effects of the deformity by proper respiratory gymnastics, etc., are the best means to nullify such predisposition, remains to be shown by future observations.

THE PASSING OF SUPERALIMENTATION IN TUBERCULOSIS.

UP to within a comparatively recent period, forced feeding was regarded as perhaps the most important element of the therapeutic tripod in tuberculosis; and even to-day many practitioners regard it as a triumph of good management if they can get two quarts of milk and half a dozen raw eggs into a stomach which is already laboring with the disposition of three or four hearty meat meals a day. The laity, always slow to unlearn hygienic errors, continue almost without exception to overfeed the phthisical, and resent, as opposed to logic and common sense, the most modern teaching that a surfeit of protein weakens the patient and favors the progress of the disease.

The origin of this practice of stuffing the tuberculous is not hard to trace. The foundation of it was the fallacy, not yet fully recognized as such, that the more food a man eats, especially the more protein he swallows, the better nourished he must of necessity be. Another fallacy which gave support to the practice was the belief that a fat man is a healthy man. The observation that tuberculosis is a disease preeminently of the herbivora and that carnivora seem to be immune, was also a factor in establishing the therapeutic doctrine of overfeeding with flesh meat. Finally it was a matter of frequent observation that when, by open-air treatment or good management in other ways, the appetite and digestion of the tuberculous were bettered so that they were able to take sufficient food, an improvement often followed in their general and local condition. Then with the illogicality of the dispensary patient it was argued that if a little food was a good thing, a lot of food must be better. The example of the Strasburg geese, with their diseased livers beloved of short-lived gourmands, was forgotten or ignored. Such an easy and logical prescription as to force food on the poorly nourished impressed physician and patient alike and an eager striving after fatness was begun. The plan was put in execution in hos-

pitals and sanatoria and was copied by physicians and the laity in private life, and much increase of suffering resulted therefrom.

Superalimentation rests upon fallacious theories, and in practice is productive of great harm. Set a theory to kill a theory, however. One of the most popular and appealing theories favored by the medical practitioner of to-day is that of autointoxication, especially intestinal autointoxication, as a cause of disease and of a lowering of the resisting power of the individual. But adherence to this doctrine is obviously incompatible with a belief in the restorative effect of overfeeding. It is plain that one cannot stuff the alimentary canal with great quantities of putrescible proteins without danger of absorption of the poisonous products of intestinal putrefaction. As a matter of fact the fever is often increased by the eating of great quantities of meat or of eggs, and indeed it sometimes appears to be caused by that alone. The digestion is also taxed to the utmost, intestinal disorders are frequent, and hepatic congestion may be pronounced. Another and very real danger of superalimentation is kidney disease, and biliary and renal lithiasis, diabetes, and various cutaneous disorders are common results of an excessive flesh diet. To sum up, in the words of Labbé in a recent article in the *Medical Press*, "excessive nourishment, especially in the shape of meat, is apt to give rise to a whole series of disturbances, some mild, some grave, some early, some late. The practitioner should be on the lookout for these, so as to combat them at the onset. They may be recognized by certain symptoms. The facies is florid, and often somewhat flushed, and there is a tendency to varicose veins; the breath is foul, presenting a characteristic odor recalling that of the breath of carnivorous animals; the tongue is coated with yellowish fur; digestion is labored, and is accompanied by a feeling of weight, by epigastric distention, and somnolence. The urine has a strong odor, and is dark in color. Lastly, albumin is often present." Such patients are prone to suffer from elevation of temperature, sometimes of a hectic character, which is wrongly attributed to overexertion, and rest is counseled with the result that the evil effects of the excessive meat diet are increased many fold.

Fortunately the evils of overfeeding in tuberculosis are now recognized by the majority of therapeutists, and most modern authorities recommend caution in this respect. The patient is no longer told to eat all he can and then a little more, but the diet prescription is now, or should be, as carefully thought out as that for climate or drugs. If the patient is of normal weight or even a little under it, and is not losing flesh, his diet is evidently sufficient for his needs and nothing is to be gained by increasing it. If he is over weight and still gaining, the diet should be reduced, for an undue amount of adipose tissue is of no advantage to the tuberculous. If there is rapid loss of flesh, in spite of a full dietary, nothing is to be gained by adding to the amount of food, but the cause of the disordered metabolism must be looked for with a view to its correction if possible. Of course if there is anorexia or indigestion the problem of the physician will be to provide for better nutrition by stimulating the appetite and promoting digestion. But with the increase of food there should be no disproportionate increase of proteins. The evil of the past has been a protein surfeit.

POST-GRADUATE INSTRUCTION IN OTO-LARYNGOLOGY.

In the latest issue of the *Laryngoscope* this subject is discussed by Dr. George E. Shambaugh of Chicago, who makes a plea for a higher standard of instruction than has yet been reached, or at least insisted on, in our post-graduate institutions. They have, he says, filled a useful place, but like the proprietary medical schools their period of usefulness has largely disappeared. The time has passed when a practitioner should drop his general work for which his medical training has prepared him and limit his practice to a special field with no other preparation than a few weeks' attendance at a post-graduate school or a short trip abroad. The writer incidentally condemns the practice of some general surgeons in operating on the mastoid for the relief of complications arising in the course of chronic suppurative otitis media. He might just as well assume to be his patient's dentist. No one should operate on the ear unless he has given to the study of its anatomy the time and attention which only the well trained specialist has done.

The author insists that the time is ripe for a revolutionary change in our attitude toward the preparation of the specialist. One of the most urgent problems in medical instruction to-day is the establishing of courses which will properly equip men for special practice. The anatomy, physiology, and pathology of a specialty must be the foundation stone of such instruction. These subjects must be thoroughly mastered before clinical study can be profitably undertaken. We have at present, Shambaugh insists, no provision for work of this kind. Our post-graduate institutions give but a smattering of clinical instruction, and often it is not as thorough as the work in special fields now being required in our leading undergraduate schools. Adequate courses can be given, he adds, only in our large schools with university connections and ample laboratory facilities.

Long ago Burke taught us the impossibility of indicting a whole nation, and the principle of this aphorism is not without its application here. We believe it possible for such ideal instruction as that outlined in the writer's argument, with the main ideas of which we fully agree, to be obtained in more than one institution in America. The trouble is more with the student who seeks the short cut to knowledge. The first specialists did not have the advantage of those of the present time. They were in a sense self-made men who had a splendid ground work of general medical information and experience, and who knew how to study, and with their meagre facilities they accomplished most commendable results. It would doubtless be found that they did just what is advised by Dr. Shambaugh—

studied as best they might special anatomy, physiology, and pathology. The part is not greater than the whole, and no ideal specialist can be made who has not had some general practice. No one should take up a specialty without at least having served in a large hospital. On this foundation his special studies may properly begin.

We need a better systematization of facilities in many of our institutions, so that a man may the better conserve his time and energies. Most of all, we need on the part of the post-graduate student a clear conception of what he has come to the post-graduate institution for. There are many attractions here and there which will but divert his energies, and he needs a greater power of concentration than the average man possesses. Hence, while there are scattered over the country men who limit their work to this or that field of medicine, there are but few well grounded specialists, according to the ideals of the writer whom we have quoted. But he has done well in calling our attention to our pedagogical weaknesses.

Fatty Degeneration of Organs.

Long ago the father of modern pathology, Rudolph Virchow, taught that the fatty changes in the parenchyma of organs may be due either to the degeneration of the cells and their transformation into fat or to their infiltration by fat brought from elsewhere in the body. In an article in the *Berliner klinische Wochenschrift* for January 21, 1909, Dr. G. Klemperer discusses this view in regard to one organ, the kidney, and shows that the views of Virchow must undergo a serious modification in the light of the results obtained by modern chemical methods. Thus Rosenfeld has shown that the degeneration of cells into fat does not take place in any such manner as suggested by Virchow; he succeeded in producing fatty changes in the liver after feeding dogs for a long time on mutton fat. The fatty substance found in the degenerated cells of the organ proved to be this foreign fat brought from other parts of the body. The occurrence of fatty changes observed in the spontaneous autolysis of organs removed from the body seems to oppose these findings, but Kraus has quite recently shown that the amount of fat in the organs after such an autolysis is in reality less than previously, which fact excludes, of course, the possibility of the appearances noted above being due to fatty degeneration of cells. Klemperer took the trouble to obtain a perfectly normal kidney and estimate its normal fat content. Like examination of diseased kidneys showed that the appearances that are usually regarded as fatty may be due to two quite different processes. One of these is fatty infiltration in the sense of Virchow, that is the deposit in the kidneys of fat derived from other portions of the body; the other altogether different in character, depending upon the deposition not of fat but of liquid substances such as cholesterin and lecithin. Both processes may exist in kidneys that are quite competent functionally. Klemperer concludes, therefore, that the grave prognosis founded upon the appearance of epithelial cells in the urine that seem to have undergone fatty degeneration is not always justified. While an abundant deposit of such character may be regarded as an indication of extensive fatty degeneration, occasionally such degeneration may not give any symptoms. Small amounts of such a sediment are of little significance in prognosis.

The Method of Mosetig in the Treatment of Bone Cavities.

In the treatment of bony cavities one of the first requirements for a permanent cure without deformity is some method of replacing the bone that has been lost by disease. This has not been found an easy matter. It is generally found to be impossible for nature to supply immediately sufficient material to produce a solid structure where much tissue has been lost in the interior of a bone It is necessary to find some material that will not act as a foreign body in the tissues, or cause suppuration, and that can be gradually absorbed, acting for a time as a splint and allowing of a gradual formation of new bone in the cavity. In the *Journal de Médecine de Bordeaux*, for December 27, 1908, Codet-Boisse describes the method proposed by Mosetig for filling bony cavities with an iodoform mixture, which has been very successful. The Congress of Surgery held at Paris during the past summer considered this subject, and all the surgeons who had made use of it expressed their satisfaction with the results. To obtain success with this method the most minute asepsis is necessary in preparing the cavity which is to be filled with the mixture. The mixture is composed of iodoform 60 grams, oil of sesame and spermaceti each 40 grams. When cold it is a solid mass, but when heated in a water-bath to 50° C. (122° F.) it becomes liquid and may be poured into the cavity in this condition. It is progressively absorbed by the walls of the cavity and its place taken by new bone. The advantages of this substance are its introduction while liquid, the antiseptic and therapeutic effects of the iodoform, and that the substance is absorbable and eliminable. In a few cases primary union of the skin wound is obtained. Generally the union is complete except at certain points where a brownish fluid flows out for a time; later granulation and cicatrization are complete. This consumes from three to eight weeks. In some cases union is not sufficient and we are able to watch the process of absorption and replacement going on in the cavity. In rare cases the mass is extruded entire. This method is applicable in osteomyelitis of the chronic variety, whenever it is possible to render aseptic the entire cavity. It fails when there are several foci of the disease. It is still more useful in tuberculous cavities that are extraarticular.

Heated Air in Medicine.

Greater efficiency is claimed for the electric light cabinet as a source of heat than for vapor or hot air baths. Heat applied in this manner is pleasanter to the patient, is well tolerated, and acts as a regulator of the circulation and a nerve tonic. Delherm and Laquerrière in the *Gazette des Hôpitaux*, for November 24 and 26, 1908, advocate its use in the general and local application of heat. Sweating is established slowly and the sweat is gradually evaporated by the heat. The lymphatics as well as the blood vessels of the surface are dilated and excretion of urea is increased. As a local application it may be used to relieve pain in neuralgia, rheuma-

tism, and lumbago. In skin diseases it relieves pruritus and eczema, and improves the condition of atonic wounds. It exercises a resolutive action on periarthritis, arthritis guttosa, and chronic edemas. The fatigue and tendency to syncope of the hot air bath are absent. In obesity it is possible to obtain a considerable reduction in weight without bad effects on the general health. In intoxication and the morphine habit disintoxication is obtained with elimination and without weakness. In fact these authors laud this method of treatment in many painful and nervous affections, and regard it as superior to most if not all of the other measures which have been advocated for their eliminative, analgesic, and sedative effects.

News of the Week.

Lectures on Sanitary Science and Public Health.—During the month of March the following lectures will be given in the course on Sanitary Science and Public Health conducted by Columbia University. The lectures are delivered at the College of Physicians and Surgeons, 437 West Fifty-ninth street, at five o'clock in the afternoons, and are open to the public. March 1, Reinforcement of Vital Resistance, by Dr. Simon Flexner, of the Rockefeller Institute; March 3, Public Health Problems of the Municipality, by Dr. Walter Bensel, of the Department of Health; March, 10, Public Health Problems of the State, by Dr. E. H. Porter, State Commissioner of Health; March 15, Public Health Problems of the Nation, by Dr. Walter Wyman, Surgeon-General, Public Health and Marine-Hospital Service; March 17, Milk Supplies and Public Health, by Dr. W. H. Park, Director of the Research Laboratories of the Department of Health; March 22, Infant Mortality and Its Reduction, by Prof. L. E. Holt, of Columbia University; March 24, The Prevention of Tuberculosis, by Dr. H. M. Biggs, of the Department of Health; March 29, School Hygiene and Sanitation, by Dr. John J. Cronin, of the Department of Health; March 31, Street Cleaning, Garbage Collection, and Refuse Disposal, by Dr. Walter Bensel.

Prizes for Typhus Serum.—The Mexican Academy of Medicine has offered $50,000 in prizes for the discovery of means of preventing typhus fever. Twenty thousand dollars is to go to the discoverer of a specific that will cure the disease; a like amount to the person discovering a serum that will kill the germs in the blood; and $10,000 to those who have aided the winners of the first two prizes.

A Healthy Town.—Higham-on-the-Hill, a village in Leicestershire, England, with a population of about 600, has a remarkable record for 1908, not one death having occurred during the year. The parish churchyard is notable for the number of octogenarians buried there, including seven of one family.

Brooklyn Doctors Protest.—The Kings County Medical Society and the Kings County Homeopathic Medical Society have joined in a protest against the recent action of Commissioner Darlington in removing the assistant sanitary superintendent from the borough of Brooklyn and transferring the records to the central office in Manhattan. The societies also condemn the dropping of measles from the list of contagious diseases.

Courses in Psychology.—The second international course in legal psychology and psychiatry will be given at Giessen, Germany, from April 13 to 18, 1909, under the direction of Dr. Sommer, Professor of Psychiatry in the University of Giessen. A two weeks' course in the problems concerning feeble-minded and psychopathic children will also be given in the Neurological Institute of Frankfurt a. Main during the latter part of June. Detailed information may be obtained from Dr. H. Vogt, Neurologisches Institut, Gartenstrasse, Frankfurt a. Main.

Sixteenth International Medical Congress.—The Secretary-General of the Sixteenth International Congress which will be held in Budapest, Hungary, from August 29 to September 4, announces that manuscripts of papers to be presented to the Congress must be despatched by February 28, at the latest, to his office, 8 Esterhazy-utcza 7, Budapest. The subscription to the Congress is twenty-five crowns in Austro-Hungarian currency, which sum may be sent by post office money order to the treasurer of the Congress at the same address.

Radium Institute in Germany.—A gift of $32,500 recently made to the University of Heidelberg is to be applied to the foundation of the first radium institute in Germany. Prof. Philip Lenard has been named as director.

Bellevue Fire Force.—A local force to fight fire has been organized at Bellevue Hospital, New York, consisting of fifty-five employees, who are being instructed by a fire drill expert. They are divided into four companies, two hose and axe companies, one chemical company, and one stretcher carrier company. A new set of signals is also to be introduced by which the steam siren in the engine house can indicate the exact location of a fire.

Hospital Heads Resign.—The trustees of the S. R. Smith Infirmary at New Brighton, Staten Island, have accepted the resignations of Dr. William C. Walser, the visiting physician, who has been connected with the institution for twenty years; of Dr. David Wilson, the chief surgeon; and of Miss Cadmus, the superintendent.

Proposed Tuberculosis Hospital.—A bill recently introduced into the New York Senate provides for the establishment of a State hospital for the treatment of intermediate and advanced cases of pulmonary tuberculosis, an appropriation of $150,000 being included to cover the cost of the site and the erection and equipping of the hospital. Preference is to be given to indigent patients, though when rooms are available, patients able to pay will be admitted. The bill provides for a governing board of five trustees, two to be physicians, appointed by the Governor.

Department of Mechanicotherapy.—The newly established Department of Mechanicotherapy at the Vanderbilt Clinic, New York, was opened on February 19. The equipment, which was the gift of Mrs. Ray Matshak in memory of her husband, consists of thirty steel machines for the exercise of every joint and muscle in the body. The department will be under the direction of Dr. Charles H. Jaeger, chief of the orthopedic division, and instructor in orthopedic surgery in the College of Physicians and Surgeons.

Dr. H. W. Lincoln has been appointed Gastro-enterologist to the Eastern District Hospital and to the Samaritan Hospital of Brooklyn.

New Police Surgeon.—Dr. Marvin R. Palmer has been appointed chief surgeon of the Police Department to succeed the late Dr. Quigley. Dr. Palmer has been attached to the department since April, 1895.

Dr. Walter C. Klotz has been elected superintendent and medical director of the Vermont Sanatorium at Pittsford. Dr. Klotz is a graduate of the College of Physicians and Surgeons, New York, and has been connected with the Stony Wold Sanatorium.

Dr. John B. Deaver, surgeon of the German Hospital, Philadelphia, was the guest of honor at a dinner at the University Club in that city on February 15, the hosts of the occasion being 150 men upon whom he had operated for appendicitis. The grateful patients presented him with a handsome silver loving cup inscribed with their names. Dr. Henry W. Stelwagon acted as toastmaster, and toasts were responded to as follows: Deaver, the Anatomist and Teacher of Anatomy, by Dr. John C. Heisler; Deaver, the Surgeon and Teacher of Surgery, by Dr. Richard C. Norris; Deaver, the Man, by Dr. Joseph S. Neff. The formal presentation of the cup was made by Dr. William E. Hughes, and appreciative remarks were made also by Dr. George W. Wagoner, President of the Medical Society of the State of Pennsylvania. Several poems appropriate to the occasion were also read.

The Alumni Association of the Lying-In Hospital.—The first meeting of this association will be held at the Harvard Club, 27 West Forty-fourth street, New York, on Tuesday evening, March 9, at half-past eight. The paper of the evening will be read by Dr. Barton Cooke Hirst of Philadelphia on "The Scope of Obstetrics as a Surgical Specialty." The secretary of the Association is Dr. J. E. Lumbard, 1925 Seventh Avenue, New York.

Westerly Physicians' Association.—At a recent meeting of this society the following officers were elected: *President,* Dr. M. H. Scanlon; *Vice-President,* Dr. Harold D. Kenyon; *Secretary,* Dr. W. A. Hilliard; *Treasurer,* Dr. C. Grant Savage.

The McLeod County (Minn.) Medical Society at its annual meeting at Glencoe on February 4, elected the following officers: *President,* Dr. B. S. Wilkerson of Glencoe; *Vice-President,* Dr. J. B. Clemens of Lester Prairie; *Secretary-Treasurer,* Dr. D. L. Axilrod of Hutchinson.

The Brainerd (Illinois) District Medical Society elected the following officers at its annual meeting, held January 28th: *President,* Dr. John M. Wilcox, Clinton; *Vice-President,* Dr. D. W. Deal, Springfield; *Secretary,* Dr. Harry S. Oyler, Lincoln. The next meeting of the society will be held in April at Lincoln.

The Danville (Illinois) Physicians' Club, recently organized, has elected the following officers: *President,* Dr. Chas. E. Wilkinson; *Vice-President,* Dr. A. M. Miller; *Secretary-Treasurer,* Dr. Benjamin Gleeson.

The Missouri Slope Medical Association, at a meeting at Bismarck, N. D., on February 3 elected the following officers: *President,* Dr. W. H. Bodenstad, New Salem; *Vice-President,* Dr. P. F. Kearney, Glen Ullin; *Secretary-Treasurer,* Dr. A. M. Brandt, Bismarck. Resolutions were passed urging the Legislature to provide for the establishment of a State tuberculosis sanatorium and condemning the proposed law permitting the sale of liquors only upon a doctor's prescription.

The York and Sunbury (N. B.) Medical Society was reorganized at a meeting at Fredericton on January 28, and the following officers were elected: *President,* Dr. A. J. Murray, Fredericton Junction; *Vice-President,* Dr. J. W. Bridges, Fredericton; *Secretary-Treasurer,* Dr. R. H. McGrath, Fredericton.

New Medical Society.—The Swedish Medical Society of Minneapolis, which was recently formed, has elected the following officers: *President,* Dr. C. J. Ringwell; *Vice-President,* Dr. A. E. Hedback; *Secretary,* Dr. Gilbert Seashore; *Treasurer,* Dr. O. A. Olson.

Gifts to Charities.—The Presbyterian Hospital and the Daisy Fields Home and Hospital for Crippled Children each receive $5,000 under the will of the late Mrs. Margaret Dows of New York, recently filed for probate. The New York Homeopathic College and Flower Hospital also receives $5,000 for a nurses' training school.

Obituary Notes.—Dr. George Rolla Highsmith of Carrollton, Mo., died at his home on January 21, from heart disease, aged 60 years. Dr. Highsmith was graduated from the Missouri Medical College, St. Louis, in 1875, and from the Bellevue Hospital Medical College in 1883. He was a member of the Americal Medical Association and the Western Surgical and Gynecological Society, and a former president of the Missouri State Medical Association and the Association of Surgeons of the Wabash Railroad. He was a lecturer on railroad surgery in the Medical Department of the University of Missouri.

Dr. Charles Everts Rider of Chappaqua, N. Y., died at his home on January 31, aged 69 years. Dr. Rider was graduated from the University of Vermont in 1863, and was a veteran of the Civil War. He was a member of the American Ophthalmological Society and the American Otological Society, an honorary member of the Rochester Pathological Society, and emeritus professor of ophthalmology in the Medical Department of Syracuse University.

Dr. Nathaniel A. Robbins of Brooklyn, N. Y., died at his home on February 16, after a long illness, aged 68 years. Dr. Robbins was graduated from the Harvard Medical School in 1864, and after serving for a time as assistant surgeon in the navy, began the practice of medicine in Brooklyn. In 1884 he was appointed Surgeon to the Brooklyn Fire Department, an office which he held until the time of his death.

Dr. Morgan Lewis Woodruff of Pittsfield, Mass., died on February 11, as the result of injuries received in a street-car accident. Dr. Woodruff was born in 1852, and was graduated from the medical department of the University of Vermont with honors in 1876, and from the Long Island College Hospital in 1878. He was one of the oldest physicians on the staff of the Mercy Hospital of Pittsfield, having served in that capacity since 1883.

Dr. Elmo Allen Hall of Mayer, Ariz., died at his home on February 1, aged 31 years. Dr. Hall was graduated from the Denver College of Medicine in 1901.

Dr. N. H. Longabough, formerly of Norristown, Pa., died at Camden, N. J., on February 16 at the age of 86 years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1849.

Dr. Thomas Lancaster died at Philadelphia on February 18 at the age of 76 years. He was grad-

uated from the Medical Department of the University of Pennsylvania in the class of 1866.

Dr. Leonard Dearth of Los Angeles, Cal., died on January 26, aged 51 years. He was a graduate of Bowdoin Medical College of Maine.

Dr. Harold Noyes of Berwick, Maine, died at his home on January 25, aged 50 years. He was a graduate of Bowdoin Medical College in the class of 1881, and had for many years served as superintendent of schools in Berwick.

Obituary.

WILLIAM TILLINGHAST BULL, M.D.,

NEW YORK.

In the death of William T. Bull, which occurred on February 22 at Wymberly, near Savannah, Ga., there has passed away one of the most deft and skilful operators that this country has had. Although learned in his science and guided in all he did by an alert brain, he was nevertheless preeminently the chirurgeon—the worker with intelligent hand, as one must be whose field of operation is largely the abdominal cavity. Dr. Bull was skilled in all surgical technique, but it was in intestinal operations, especially in the repair of the intestines after gunshot and stab wounds of the abdomen, that he made his early reputation, and he was also one of the first to perform appendicitis operations with success. He was likewise a close student of, and frequent operator for, cancer, the disease to which he succumbed after a struggle of less than a year.

Dr. Bull was born in Newport, R. I., May 18, 1849, being therefore within three months of 60 years of age at the time of his death. He was graduated in arts from Harvard in the class of 1869, and in medicine from the College of Physicians and Surgeons, New York, in 1872. After serving a term as interne in Bellevue Hospital he spent two years in study in Europe, and then began practice in this city in 1875. He was in charge of the New York Dispensary for two years, and was surgeon in chief of the Chambers Street House of Relief of the New York Hospital from 1877 to 1888. It was in this hospital, with its enormous accident service, that Dr. Bull did most of the abdominal work which first gave him fame. In 1880 he was appointed surgeon to St. Luke's Hospital, and in 1883 to the New York Hospital, resigning then from St. Luke's, for he believed that a surgeon could not hold two hospital services and do his duty to each. Upon retiring from St. Luke's he was appointed consulting surgeon to the hospital, and he was also consultant to the Hospital for the Ruptured and Crippled and to the New York State Emigrants' Hospital.

In 1879-80 Dr. Bull was demonstrator of anatomy at the College of Physicians and Surgeons, and in 1887 was appointed professor of the practice of surgery in the same institution. His final illness dated apparently from April of last year, when he was operated upon for glandular enlargement in the neck. A second operation was found necessary some months later, and in the autumn he returned from his Newport home a dying man. He made a brave fight for life, always cheerful and always hopeful, and a month ago was taken to Savannah where the mild climate would permit him to spend more time in the open air. He was of a bright and cheerful disposition, a pleasant companion, and a loyal friend, and his premature death will bring sincere grief to patients, colleagues, and friends alike.

A FRIEND'S TRIBUTE.

A great surgeon is dead. But that is not all; indeed, it is only a part of it, and a small part. Dr. Bull's great kindness and sympathy; his absolute integrity of purpose; his admirable judgment; his perfect poise and self-reliance, without the smallest shade of conceit, or littleness, in any way, made him a marked man anywhere. A handsome presence, a cordial, genial manner, a perfect consideration for others at all times, a loyalty to his friends which stood every test; an inability to pull down and slight others ever; a fair and candid appreciation of good, square work always; a readiness to do for all men at the unlimited sacrifice of himself; an upholding, under all circumstances, of the best, highest ideals of professional tone and honor—all these combined good and laudable traits made him almost unique in the present generation of surgeons of New York, of our country—the world. It will be quite impossible to replace him, at least for many a day, and the consensus of every man, woman, and child who has known him in his professional, or social relations purely, is to affirm all that is commendable of him in life, and now that he is gone, alas! from among us, to emulate closely his example and to cherish his memory ever green, as the symbol of our faith in righteousness and well-doing, forever and aye.

Beverley Robinson.

New York, February 23, 1909.

Correspondence.

THE PHYSICIANS' MUTUAL AID ASSOCIATION.

To the Editor of the Medical Record:

Sir:—A few days ago I read in the daily paper a statement that the Physicians' Mutual Aid Association had been criticised by the Insurance Department at Albany because it had made a loan to its own treasurer. The defense as given was that, owing to the association's status, it did not come under the provisions of the special rule, the violation of which was claimed. I also noted the brief reference to the matter in your issue of February 20.

Probably no one of our local medical organizations has had the greater confidence of the profession than the one in question. Whether it has violated any rule of the Insurance Department or not, is for the law to determine. But the publicity already given to the matter may undermine the faith of some, and I therefore think that a statement from its officers of all the facts in the case is distinctly in order.

Whether the association has violated any definite law or not, does it not seem at least injudicious to lend its own funds to one of its own officers, no matter how well the loan might be secured? Since the recent insurance disclosures the public mind is very sensitive about the necessity of avoiding even the appearance of evil.

Member in Good Standing.

CORRECT MEDICAL SPEECH

To the Editor of the Medical Record:

Sir:—The following lines I have had printed on a card, and sent to many colleagues throughout the country. Might I ask you to reprint them so as to give them a still wider circulation:

"Correctness of onomatology is even more an index of character in science than in daily speech. In medical onomatology, as in ordinary speech, wanton incorrectness is an offense against both truth and good manners. The uncultured mind revels in uncouth expressions. Incorrect medical onomatology is on a par with slang in ordinary speech; the use of either betrays ignorance or a mind devoid of fine feeling."

A. Rose, M.D.

New York.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

ROYAL ARMY MEDICAL COLLEGE—KALA AZAR—GENERAL PARALYSIS IN CHILDREN—ANESTHETIC QUESTION—ALLEGED MONOPOLY OF HOSPITAL APPOINTMENTS—ANOTHER VICTIM OF X-RAYS—OBITUARY.

London, February 5, 1909.

On Tuesday the Director-General of the Army Medical Department and the members of the Royal Army Medical College entertained at dinner Viscount Middleton, who as Secretary of War founded the college. Sir Alfred Keogh, Director-General, said the mantle of Lord Herbert of Lea had fallen on Lord Middleton, who had recognized how potent was the influence which an efficient medical service could exert in promoting efficiency in war and diminishing sickness in peace. The establishment of the college was designed to improve the early education of the medical officer, as well as to afford later and special opportunities for research, and there had ensued remarkable results, as in Malta fever and sleeping sickness. Diminished mortality and invaliding, with better recruiting and improved physical training of the soldier, had also followed. Extraordinary results in antienteric inoculation in India were also due to the work of the professors in the college. In many ways the latent energy of the service had become actual through the attitude of Lord Middleton, when, as War Secretary, he founded the Royal Army Medical College.

Lord Middleton, after warmly thanking his hosts and saying he was proud to be their guest, declared the medical service had no more escaped criticism than other branches. During the last war there were almost as many laymen ready to show how the hospitals ought to have been organized as there were amateur strategists to tell our generals how to conduct a campaign. After the Crimean War there was a general outcry for a reduction of the medical strength and stagnation or worse was the consequence. But the seven years since the South African War have formed a record for the service and the British army medical service now bids fair to be a pattern among the armies of the world. In this college, after seven years' service, the officers can come for six months in the most advanced studies and so not be cut off from the workers in the civil profession. This was not due to himself, but to Sir A. Keogh and other distinguished authorities from whom he received inspiration in 1901. Though so short a time established, the college had become a link between the civil and military profession, with advantage to both. Malta fever and sleeping sickness are witnesses. The discovery of the organism of kala azar, the preparation of antityphoid vaccine, and the chemical work as to food and training of soldiers have been on in the laboratory of the college and these results inspire belief in an even brighter future. It is to this college the country must look to maintain the assured position of the medical service in the army and to secure through the army for the nation those priceless results which it is in the power of medical science to bestow.

The parasite of kala azar has been the subject of discussion at the Society of Tropical Medicine. It was begun by Captain W. S. Patton, M.B., I.M.S., who has made exhaustive investigations on the organisms supposed to be responsible for this and some other diseases. He had no hesitation in rejecting the view that the parasite is a trypanosome, but is a herpetomonas. The type species of this is the *H. muscæ domesticæ*, the life cycle of which he found closely resembled that of the parasite of kala azar. He has carefully studied these and other species and concludes that the parasite of kala azar is the *H. donovani* (Laveran and Mesnil); that of infantile splenomegaly is *H. infantum* (Nicolle) and that of oriental sore *H. tropica* (Wright). He suggested that diseases caused by these parasites should be collectively known as herpetomoniases. All attempts to inoculate animals with *H. donovani* have failed and it may not be possible to prove that the carrier is the suspected bedbug. Feeding experiments in tubes of different blood-sucking insects, though interesting, are not likely to be conclusive, and the difficulties of carrying them out were mentioned by Captain Patton, who has described the development of the parasite of kala azar in the "Scientific Memoirs" of the Indian Government.

Dr. Sambon was inclined to agree with Sir Patrick Manson, who regarded oriental sore as a benign form of kala azar. The geographical distribution favored this view and the oriental sore was held to confer immunity against kala azar. The reason of the rarity of preflagellate stages was that they were only to be found after recent blood-sucture.

Dr. G. C. Low was not satisfied that the parasite was a herpetomonas, for that organism had no sexual stage and there was such a stage probably in the other parasite.

Sir Havelock Charles, in the course of a long experience on the northwest frontier of India, had not met with kala azar, but had treated many cases of oriental sore. In Lower Bengal he had many cases of kala azar. If the two were practically the same, he should expect to find them coexisting in any locality.

Dr. Wenyon would not draw a hard and fast line between herpetomonades and trypanosomes, for many varieties of the latter resembled the former in some of their stages. The observations by the French Commission on sleeping sickness seemed almost to suggest that one form passed to the other on account of different conditions.

Sir P. Manson, president, said we could not say the life history of the Leishman body was fully nor approximately complete. Captain Patton had assumed that the domestic fly infected itself by feeding on its own feces, but there was no proof that it did anything so contrary to the whole course of nature. It was possible that kala azar was not identical with oriental sore, but it was probable, and the life history of the parasite of oriental sore ought to be worked out, for it would most likely throw light on that.

Dr. Sandwith then showed a specimen of "Jeddah ulcer" for Dr. Creswell of Suez and remarked that it ought to be called "oriental sore." French writers had lately been calling it "Leishmaniose cutanee." The term "fly-bite" is applied to it in some parts by the natives, some of whom trace it to bad water, and in India it is said to have been less prevalent since the better supply. It is more common in autumn when gnats and other insects abound. A distinction should be made between oriental sore and Nile boil, which could be inoculated into a healthy man, but did not go on to ulceration and did not last for months, each boil usually disappearing in a fortnight. Mr. Madden had obtained a pure culture of *Staphylococcus pyogenes aureus* from a case in Cairo.

There was a rather gruesome exhibit at the Pathological Section (Royal Medical Society), the president showing microscopical sections he had made from a piece of the aorta of the reputed Pharaoh of the Exodus, sent to the Royal College of Physicians by Professor Smith, who unwrapped the mummy, which was found in the tomb of Amenhotop II. The sections showed typical senile calcification, the bony, parallel, elastic lamellæ being perfectly preserved, and the intralamellan material thickly strewn with calcium phosphate. King Menaphta (Pharaoh) was an old man.

Dr. P. Rondoni of Florence narrated two cases of juvenile general paralysis and one of disease of brain. All three were hereditary syphilitics. The chief histological characters were perivascular infiltration with plasma cells and lymphocytes especially marked in the cortex, but also extending to the base. In one case he excluded general paralysis on account of the absence of the appearances often called diagnostic. Dr. Mott remarked that plasma cells around the vessel were suggestive of syphilis or trypanosome disease. It was a mistake to consider it diagnostic of general paralysis. In working on sleeping sickness he had fifty blocks cut from various brain diseases in the laboratory. They were stained and put up by an assistant, and he said he would pick out the general paralysis and sleeping sickness cases from the microscopical appearances. He succeeded in thirteen cases of general paralysis and two of sleeping sickness. Dr. Rondoni's paper was important from the discovery of the changes in the perivascular lymphatics and the basal ganglia. The change was expected on account of what had been observed in sleeping sickness.

A special meeting of the Section on Anesthetics was held on the 20th ultimo to discuss the bill proposed to be brought forward which would restrict the administration of these agents to qualified medical practitioners. To the surprise of outsiders, there was no unanimity in the Section. It was proposed that the prohibition should not apply to persons who gave nitrous oxide, on the ground that dentists had been accustomed to give it. This proposition met with a seconder. Another

member opposed the bill *in toto* and did not believe the House of Commons would pass it. On the other hand, it was urged that the bill had the support of the General Medical Council. On this point you may remember that last year when the Privy Council asked for an expression of the Medical Council's opinion the president replied that the bill appeared to contain what is essential for the protection of the public in this department of practice and it would be well if it could be extended to all departments by which life or limb is endangered. The president, Sir Donald MacAlister, has been generally held to have well represented medical opinion in this pronouncement. It may, indeed, be argued that the theme touched the first need of medical reform. It may be questioned whether a bill dealing with so small a portion of the reforms needed would assist or hinder further restrictive legislation. But the deaths that have been caused by anesthetics are making an impression on the public, and it is possible Parliament may determine to do something. In that case, say some, why not accept a modicum of protection for the profession on the principle that half a loaf is better than no bread. This, however, is hardly half a loaf—only a crumb, it seems. The discussion in the Section was adjourned until this evening, when perhaps the anesthetists will assemble in full force and come to a decision.

A few holders of Scotch and Irish diplomas are again trying to get up an agitation about what they designate the monopoly of hospital appointments in England by holders of English qualifications. The grievance is an old one, according to these gentlemen, who would have us believe that they are unfairly excluded from competition. Lately they got up a meeting in London, when all their old assertions were repeated, and they threaten an active campaign, but as many such have died under the indifference of the profession, the English corporations have little to fear, even although some of the agitators talk of parliamentary interference. The existence of different qualifying bodies in the three Kingdoms is perhaps an unfortunate fact, and carries with it certain preferences. If we had only a single State qualification, and that properly protected, few would care how many academical distinctions were left or which the governors of hospitals would prefer. As it is the local, some call them national, institutions naturally obtain a preference in their several localities, and it is not necessary to make invidious comparisons. Scotch and Irish doctors practice in London as freely as any. But it does not follow that they are all the most fitted to be hospital physicians and surgeons. The governors of these charities are entitled to say what distinctions they desire their staff to hold, and the same claim would be made under a State qualification. That would be necessary; but the governors could ask for any additional diplomas, although they were only academical distinctions. The grievance seems to be like many others of the kind, quite one-sided. These agitators would do well first to ask themselves how far Englishmen and English things are *hors concours* in Dublin or in Edinburgh. We have had examples of this sort of discrimination even in medical appointments.

I regret to report another victim of *x*-ray work. Mr. H. W. Cox, the well-known manufacturer of scientific instruments, has had to have three fingers of his right hand removed. He had previously lost a finger of the left hand. I understand the dermatitis was not caused by his recent work, but at an earlier period—some of it in testing apparatus to be sent out for use during the South African War. The King has sent a message of sympathy.

The death is announced of Surgeon-Major T. J. Tucker, who entered the army as assistant surgeon in 1855, and saw service through the Indian Mutiny, being present at Dinapore, 1857; Koer Singh, thence in the advance to Lucknow and the siege and capture of the city. He received the medal with clasps for his services. He retired in 1877.

News arrived to-day from India of the death of Major W. H. Orr, C.I.E., I.M.S., at the age of 41. He served the Waziristan Expedition in 1894-95 and obtained the medal and clasps.

Dr. Evan Spicer, who was killed by an avalanche in Switzerland, was a distinguished alumnus of the London Hospital, and was appointed Registrar last year. He had a good prospect of election to the staff, but, to the deep regret of his fellows, perished at 33 years of age.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

TRANSPLANTATION OF ADRENAL GLANDS; ISRAEL'S RESULTS IN OPERATIONS FOR RENAL CALCULI; THE PATHOGENESIS OF RENAL TUBERCULOSIS; RESULTS OF SUPRAPUBIC PROSTATECTOMY; THE CONTROVERSY OF PHYSICIANS WITH THE LIFE INSURANCE COMPANIES.

BERLIN, January 15, 1909.

THE meeting of the Berlin Surgical Society that took place on December 14, 1908, proved to be a very important scientific event; Professor Israel presided that evening and the entire program consisted of papers prepared by him and by his assistants. Dr. Neuhauser reported a successful experiment which has not been duplicated by any other worker. He has tried to transplant adrenal bodies removed from embryos into the kidneys of rabbits; at first, the pieces thus transplanted were absorbed in every case. Finally, he decided to transplant the adrenals of rabbits that were only a few days old, and was rewarded with signal success. Dr. Neuhauser demonstrated first some serial sections of the adrenal body of a very young rabbit, which showed the presence of large epithelioid cells with clear protoplasm that were not unlike the cells found in the hypernephromata of the human being. A second picture showed a complete section of a rabbit's kidney into which adrenal tissue had been implanted; the upper part of the organ contained some tissue that was quite different from that of the kidney proper. Microscopically this tissue proved to consist of cells that were similar to the cells of the adrenal body mentioned above. Larger magnification of the tumor tissue showed several places at which the renal substance proper was being invaded by the cells of the neoplasm, the invasion taking the path of the capillaries of the organ. This preparation showed that, at last, the experimental production of an adrenal tumor has been successfully carried out, the destructive character of the new growth being proved by the microscopical appearances detailed above.

The same speaker addressed the meeting on the "Results of Operations for Renal Calculi," the material of Israel's practice having been used by him for the paper. The general mortality reached 12 per cent. of the cases; this figure appears quite high when the vast experience and skill of Dr. Israel is considered, but it must be remembered that a number of patients that are sent to Israel for operation reach Berlin in very poor condition, and that no case is turned away without operation if there is the least hope that a surgical procedure might prove beneficial. In reference to the prognosis of postoperative hemorrhage Israel's figures show that whenever a secondary nephrectomy had to be performed the mortality was much greater than in cases in which simpler measures, such as tamponing of the wound, were successful in stopping the bleeding.

Israel and Schneider spoke on the "Pathogenesis of Renal Tuberculosis"; according to them most cases of renal tuberculosis begin with the invasion at the apices of the renal pyramids. Preparations of early tuberculous material showed many instances in which the pelvis of the kidney had not been attacked by the infection while the apices of the papillæ were already in the primary stages of the disease. As this primary grade of tuberculous infection is characterized only by a light swelling of the tissues and by changes in staining reactions it is quite evident that such changes could very easily escape the attention of operators not versed in renal pathology. The next stage of the disease is characterized by the development of cavities in the pyramids, which are, of course, easier to recognize.

Dr. Bloch spoke on the subject of "Ureteral Calculi," and reported the cases operated upon in the clinic under the direction of Israel, giving description of the technique employed. Dr. Cahn spoke of the clinical and histological data obtained from the study of some forty cases of suprapubic prostatectomy. The following conditions are regarded in Israel's clinic as indicating the operation in question: Grave disturbances in the function of urination that cannot be dealt with by conservative treatment and become almost unbearable for the patient. Among these are included cases in which the use of the catheter is not accompanied by any improvement in the bladder disturbance, either because residual urine cannot be every time removed by catheterization or because inflammation of renal pelvis occurs or, finally, because dysuria and tenesmus are not avoided by the use of the catheter. Other cases are selected, among those mentioned in which catheterization is impossible either because it is attended with serious hemorrhages and intense pain or because of the existence

of false passages in the urethra that make the use of a catheter dangerous. A third set of cases in which operation is indicated belong among those persons in whom the use of a permanent catheter could not be carried out without inviting quick infection of the urinary organs. Grave hematuria is also looked upon as indication for the removal of the prostate even though it may appear without being accompanied by disturbances of urination or any other difficulty.

In all forty operations the technique of Peyer's suprapubic enucleation of the gland was followed. Six patients died soon after the operation one of them of anuria and uremia, one of diabetic coma, two of pulmonary embolism, one of pneumonia, and one of peritonitis. Of the thirty-four patients who bore the procedure well, thirty-two were cured, that is, they could empty their bladders in the normal intervals of urination and without experiencing any difficulty in the act. Two patients suffered from incontinence of urine at the time of their discharge.

The histological findings, which were illustrated by lantern pictures during the delivery of the paper, are very interesting, because of the fact that in all forty specimens, Dr. Cahn has found adenomatous structures resembling papillary adenomata. Dr. Cahn concludes from these findings that hypertrophy of the prostate gland depends upon adenomatous changes in the glandular epithelium; this view is in agreement with the observation that a recurrence of the hypertrophy can take place even after a supposed total removal of the gland as well as with the fact that frequent carcinomatous changes are found in the gland. The latter changes were very well demonstrated by some of the pictures that showed various portions of the same hypertrophied gland.

The last few weeks of the past year brought with them very important developments in the professional relations of German physicians to insurance companies. The last Physicians' Congress decided to look for means of obtaining better remuneration for services rendered to life insurance companies, and the Leipsic Union has been carrying negotiations in this direction. The Assocation of Life Insurance Companes, however, declared that the Leipsic Union was not, in its opinion, the proper bodv to carry on these negotiations, and refused absoluetly to have anything to do with it. This, of course, meant a declaration of war for the German physicians. The Leipsic Union directed the physicians to furnish certificates for life insurance companies only at much higher rates than were charged for such service before, and to refuse to perform the service in question altogether if the bills were not honored. The resolution was carried out, the German profession proving that it was united in the defense of its justifiable demands for better remuneration of professional services. On the 28th of December a new agreement was finally arranged, according to which the pay of physicians for serving life insurance companies was increased, and in addition it was agreed that a permanent committee should be formed, to consist of three members of the Leipsic Union and of as many representatives of the Union of German Life Insurance Companies in order that permanent arrangements should he made in regard to the question at issue.

OUR LETTER FROM COPENHAGEN.

(From Our Regular Correspondent.)

COPENHAGEN, January 31, 1909.

AT a joint meeting of the Danish Surgical Society and the Danish Otolaryngological Society Prof. Holger Mygind read a paper on otogenic meningitis, with special regard to its operative treatment. During the last two or three years he had observed 21 cases of otogenic meningitis and had operated in 16 of these, with the result that 5 of the patients operated on recovered. The diagnosis was based not only on the usual clinical symptoms, of which he had found the most reliable to be Kernig's symptom and the retraction of the head, but in every case had lumbar puncture been performed and the cerebrospinal fluid evacuated had been turbid in its appearance and had presented on microscopical examination an increased number of polynuclear leucocytes and often microbes, especially pneumococci. Lateral sinus thrombosis often occurred as a complication, and cases of this class seemed to possess the most favorable prognosis, perhaps because the sinus thrombosis was the connecting and transmitting link between the suppurative otitis and the meningitis, while at the same time it was possible to eradicate the infected thrombus far more thoroughly than an operation, for instance on the labyrinth, could hope to do in cases in which the meningitis had been induced by a labyrinthitis. As to the treatment Professor Mygind recommended to follow the method which he had adopted. After complete radical operation of the middle ear and mastoid process, a large craniotomy opening is made in the middle and posterior fossa cranii, so that the dura mater is exposed in a rather large area. Next, a crucial incision of the dura gives access to the subdural space, so that a possibly existing subdural abscess may be found and emptied. The third stage—not always carried out—is incision of the temporal lobe or cerebellum in order not to fail to discover a latent cerebral abscess. There is no great escape of cerebrospinal fluid during or after the operation, as the cerebral substance bulges as a rule into the craniotomy opening, thus in a way shutting off the subdural space from the mastoid wound. Therefore, Professor Mygind does not make the incisions through the dura mater in order to drain the subdural space, but chiefly in order not to fail to discover localized subdural inflammatory processes.

Dr. P. Tetens Hald communicated a case of meningitis arising after a radical operation of the middle ear, in which he had been able to demonstrate intravitam by means of the modern labyrinthine tests that the infection had passed from the middle ear through the labyrinth to the meninges. Besides opening the subdural space, he had therefore performed a radical exenteration of the labyrinth, but had failed to save the patient. He stated his view as to operation of the labyrinth in cases of otogenic meningitis to be the following: Where the clinical examination shows destruction of the labyrinth, it is of course always necessary to operate on it. If the clinical examination does not show any such destruction, there are two eventualities. Either the operator finds during the operation intracranial complications capable of explaining the arising of the meningitis, for instance a sinus thrombosis; in this case it is sufficient to operate on this complication and await the further course of the disease. Or there is not found any such complication; in this case Dr. Tetens Hald proposes as a rule to operate on the labyrinth, because it may without doubt be infected and transmit infection to the meninges, though the clinical examination fails to demonstrate a destruction of it. The patient will therefore have a greater chance of recovery when the labyrinth is operated on in these cases. Of course, it will then also occur in some cases that a really healthy (i.e., not infected) labyrinth is opened. But as the operation of the labyrinth in itself is not a danger to the life of the patient, and in these cases the function of the labyrinth is nearly always impaired, Dr. Hald estimates that the operator ought to run the risk of operating sometimes on a not infected labyrinth in order to give his meningitis patients in every case all the possible chances of recovery.

Professor Tscherning said he had operated on otogenic meningitis as far back as 1895, but during the first years all his patients died. It was essential to operate at the earliest possible stage. He believed more in draining the subdural space than did Professor Mygind, and he lifted therefore the brain away from the underlying structures and interposed strips of iodoform gauze. He congratulated Professor Mygind on his results, which he considered encouraged operating in every case where the patient could possibly stand the operation.

Progress of Medical Science.

Boston Medical and Surgical Journal, February 11, 1909.

Human Milk in the Treatment of Various Infections.—F. P. Denny finds that human milk is of great value to infants in increasing their resistance against infections of the gastrointestinal and respiratory tracts and against sepsis. He finds it can be employed just as we use antitoxins or bacterial vaccines. In many cases in which human milk is given to infants because they are thought not to be able to digest cow's milk, the real cause of the trouble is a gastrointestinal infection. The presence of undigested food in the bowels does not necessarily cause symptoms, but rather leads to bacterial growth in the intestinal contents and the toxic material resulting therefrom acts on the digestive glands and impairs their functions. Very frequently the substitution of human for cow's milk in such cases will increase the infant's resistance toward

infection, and symptoms promptly subside. So also with bronchopneumonia and subacute skin infections, like tuberculosis. As to obtaining human milk, it must frequently be drawn from the breast and fed to the child. Among a large number of nursing mothers there are always a few who have an overabundance of milk. The author says that a large city needs some registry for wet nurses and which might keep a list of women who could furnish breast milk when called on.

The Serum Diagnosis of Syphilis.—F. P. Gay and J. L. Fitzgerald epitomize recent literature on the subject and give comparative results with the Englobin, Noguchi and Wassermann methods. From the result of their work to date they conclude that a positive Wassermann reaction with blood serum or cerebrospinal fluid is diagnostic of syphilis, but that a negative reaction, particularly in the tertiary stage, is of little absolute value. The Wassermann reaction is usually present in secondary syphilis and less frequently in tertiary syphilis and parasyphilitic conditions. The probable effect of treatment on the Wassermann reaction may explain the fact that the reaction is not so frequent in the tertiary stage. The Noguchi method as applied to the cerebrospinal fluid gives a positive result in syphilitic meningeal complications in many more cases than does the Wassermann reaction. But although it fails to give the reaction in many cases without meningeal complications, it may give it in any case that shows them. The reaction is therefore probably of value chiefly as an adjuvant in the differential diagnosis of general paresis. The authors tabulate the results of their own work and append a brief bibliography.

New York Medical Journal, February 13, 1909.

Four Hundred Operative Cases of Mastoiditis.—The results in this series of cases which occurred in the New York Eye and Ear Infirmary are analyzed by F. P. Calhoun. The Schwartze and Schwartze-Stacke operations are contrasted and the results compared in the work of some twenty operators on a class of patients whose home surroundings were, as a rule, most unfavorable. A careful analysis is made of etiology, symptoms, bacteriological findings, operative accidents, complications, etc. Of the Schwartze series, results are known in one hundred and eighty-six of the two hundred and seventy-one cases. The shortest time of healing was thirty-four days, and the longest was one year. This last case was in a tuberculous patient. On the other hand, there was another tuberculous patient in a more advanced stage whose wound healed in six weeks. The average mastoid healed in ten weeks. One hundred and twenty-six patients were cured. Seventeen were in a state of healing when last seen. Fourteen did not heal, and when last seen had posterior discharging sinuses. The posterior wound healed entirely, but the aural discharge still continued in eight cases, and there were twenty-one deaths. Of the fourteen cases that did not heal, fifty per cent. were in children or infants under five years. The only explanation offered for this failure is the fact that they were neglected by their parents when dismissed from the Infirmary, and did not report promptly for clinical dressings or observation. Five of this number required secondary operations (Schwartze-Stacke). Of the Schwartze-Stacke series of eighty-one cases, results were followed in sixty-four. The average time of healing was about four and one-half months. The longest was nine months. The shortest forty-nine days. The ten cases grafted did not give the results as one would ordinarily expect. The majority of the grafts sloughed. The shortest time of healing with a skin graft was three months. Thirty-nine cases healed completely; eight patients were in a state of healing when last seen, two months after opertion; ten were discharged with no prospect of a permanent cure; seventeen were lost sight of; seven died. The deaths were due to the following causes: One case of diabetic coma following operation; meningitis in two cases; brain abscess with meningitis in one; sinus thrombosis (operative); sinus thrombosis (unoperative), and cavernus sinus thrombosis. The Stacke operation was done in forty-eight cases for relief of chronic aural discharge with or without other symptoms. The results are tabulated, grafts having been used in twenty cases. Four healed; three were healing three months after operation; eleven were discharging from three to eleven months after operation, and two were lost sight of. Of the cases not grafted, thirteen healed, four were healing, three months after operation; five discharging at periods as above indicated, while six were lost sight of. The author's paper is a careful study of valuable material.

Diagnosis of Chronic Bright's Disease by Signs Other Than Those Furnished by the Urine. H. B. Allyn considers the subjects of cardiovascular signs. Light arterial pressure, thickening of blood vessels, enlargement of the left ventricle, hemorrhage, albuminuric retinitis and retinal detachment, dizziness and vertigo, nutritional changes, tone phenomena, coma, convulsions, paralysis, delirium and peripheral neuritis. Summarized histories are given of five cases illustrative of the points made by the author. He regards the cardiovascular signs as perhaps the most important and constant, and includes under this heading several of the foregoing, such as cardiac enlargement, vascular thickening, accentuated second aortic sound, etc. The author believes that in the vast majority of cases the urine, if repeatedly and carefully examined, will at some time show albumin or casts, or both, or will have a persistent low specific gravity, yet in a few cases it will give us no help in diagnosis or may mislead us into thinking that the kidneys are sound. Moreover, in hospital cases particularly, we must often make a diagnosis in a short time and with very inadequate previous history. It would be better to regard the condition of the urine as only a part of the clinical picture of chronic Bright's disease, and not necessarily and always the most important. But experience in and out of the hospital convinces me that too much dependence is placed upon an examination of the urine and too little attention paid to the general phenomena of the disease. The net result is that Bright's disease is often overlooked and the patient treated for heart disease, anemia, or weakness and malnutrition of unknown origin. These are the considerations which have induced the writer to endeavor to present the extra-urinary phenomena of Bright's disease, in the belief that by them we can often diagnose the disease even when the urine is negative.

Neurasthenia.—A brief general article is presented by H. M. Folkes, who notes the disturbed mentality, the most notable manifestation of which is the tendency of the patient to constantly dwell upon his condition. He usually believes that he is the only person who has ever had the exact symptoms he presents. No opportunity is lost to impress upon the physician the gravity of his especial case. His sense of proportion is usually markedly impaired and he does not dare to undertake things, the execution of which, to the normal mind, is trivial, as it assumes alarming characteristics from his viewpoint. Prominent among the other mental symptoms presented are fear of being left alone, making a journey, or even walking from one room to another. These subjects dwell in large measure upon their inability to earn a living. Nearly all of them have insomnia. About a third are decidedly emotional. Fully a third have periods of depression, loss of memory, inability, at times for maintained effort, loss of confidence, and irritability. The physical symptoms are endless, appearing as fatigue, weakness, tremor, paresthesia, headache, dizziness, anorexia, anemia, dyspepsia, constipation, flatulence, pain in various parts of the body, vague, ill defined feelings, impairment of the special senses, cold extremities, cold sweating, and impairment of the reflexes. Young women who have been overworked at college, as well as the housewife, frequently display many of the pelvic symptoms common to their sex. Relapses are the rule. Treatment should discard all drugs unless absolutely necessary. We must never lose our grip on the patient's mentality, for herein lies the key to success.

A Case of So-called Birth Mark.—F. A. Thompson recalls the case of an intelligent woman of 30 years who in the third month of her gestation was hanging a picture on the wall (being on a stepladder) and was accidentally precipitated to the floor, on the way striking her forehead on the edge of a chair. There was a mark on the forehead, red swollen between the eyebrows and up on the forehead about two inches. It extended over the orbit on the left side so that the upper eyelid was swollen and later black. In due time the patient was delivered of a healthy male child of normal build and size. The period of labor was normal, not protracted, no instruments being used. At birth there was a very small and faint red mark on the baby's forehead, but as the mother's fall had been forgotten, it was thought to be a parturient accident, and the parents were told that it would disappear. A few days later the mark was if anything plainer, and is still

there. It is a finely lined collection of dilated capillaries and occupies the exact position of the mark that the mother had. Another peculiar fact was brought out in talking the matter over with the mother recently. She states that she noticed at the time of the fall a sore spot on the occipital region. She paid no attention to it, as she reasoned that she had bumped herself in the fall. The child now has on its occipital region a mark similar to the one on the forehead. This was discovered a few days later than the one previously described.

Journal of the American Medical Association, February 13, 1909.

Tropical Diseases.—R. P. Strong describes the results of scientific methods of combating tropical diseases in Manila since the American occupation. Tropical dysentery, of which no accurate knowledge had previously been obtained, was found after an extensive research to include three different affections, requiring different treatment—amebic dysentery, due to a protozoan; bacillary dysentery, with an acute onset, and apparently the same as that prevalent in Japan, and lastly catarrhal dysentery, corresponding to the forms prevailing more or less throughout the world. Each of these can be recognized by laboratory methods and the treatment modified accordingly. The first two forms were found to be acquired usually by drinking infected water, and the catarrhal form was at least frequently contracted in this way. It was found, moreover, that the city water supply was practically always infected with amebas, which cannot be destroyed by chemical methods or filtration, hence it can only be safely used for drinking purposes after sterilization. The results of these researches, however, have been that the mortality and the amount of dysentery among Americans and Europeans has been greatly reduced, and bacillary dysentery, which formerly was epidemic, and which frequently carried off its victims in from three to four days, has become a rarity, and amebic dysentery is becoming less and less frequent every year among the more intelligent population. Strenuous methods were adopted at once against plague on its introduction in 1900, and a method of antiplague vaccination has been devised which will probably reduce the mortality to under 20 per cent. At present there has been no case of plague for over a year. Cholera has also been largely controlled, in spite of bitter opposition on the part of the natives, who were inclined to conceal every case. It still exists, and may be considered endemic in the islands; but, while the present hygienic measures are enforced, there is little danger of any large epidemic. It seems not unlikely that in protective inoculation we have a valuable aid in freeing a community from this disease, and that more and more reliance will be placed upon it in the future. It has been found that about 50 per cent. of the children in certain portions of the islands suffer from a latent form of malaria and that in some districts over 50 per cent. of the adults have the disease in an active or latent form. The amount of anemia and general debility thus produced has been greatly underestimated. In certain portions of the islands such measures as the discovery of these latent cases by routine microscopic examination of the blood and treatment of the patient, play an important part in the work for the suppression of malaria. Malaria is uncommon in the white population, however, especially in the large towns. Studies in dengue fever, recently made, seem to show that its ultramicroscopic organism is conveyed by the bite of the mosquito, *Culex fatigans*, which also conveys the filaria of elephantiasis. Infection with intestinal parasites, especially amebas and hook-worms, appears to be prevalent in the natives, but the hook-worm infection does not seem to have quite so serious consequences in causing grave anemia as it does in Porto Rico and some other regions. Both of these organisms, however, are pathological and may be of serious importance. The methods of satisfactorily disposing of human dejecta, so as to control these infections, present a problem that will require considerable study and is now being investigated. Over 3,515,000 people have been vaccinated against smallpox, without any serious case of infection from vaccination being reported, and with the result of a great decrease of smallpox mortality. In provinces where there were formerly 6,000 cases annually, not one death from the disease has been reported during the past year. The disease has been kept thoroughly under control by vaccination alone. In conclusion Strong says: "After nearly ten years' residence in the Philippines, I think that I am justified in saying that Manila to-day can certainly be regarded as a very healthy city for those who exercise proper hygienic precautions in regard to their mode of living. The death rate here for the past year among American residents has been only 5.59 and among Spaniards but 15.84 per 1,000."

Tuberculosis vs. Paresis.—A. J. Rosanoff states that while the death rate from tuberculosis is high in the patients of the hospital from which he writes, he has for several years had his attention called to the fact that paretics that came to autopsy were remarkably free from tuberculous lesions. This observation was almost constant and he went over all the autopsy records and found that they strikingly corroborated it. As the total number of cases, however, was small, he availed himself in addition of the autopsy records from the State hospitals at Ward's Island, Flatbush, Middletown, and Buffalo, including 1,056 autopsies, 214 of which were cases of general paresis that are also tabulated. It shows that while active lesions were found in 23.2 per cent. of other psychoses only 2.3 per cent. of the paresis cases showed the presence of active tuberculous lesions. He also tabulates the data in such a way as to show the frequency of tuberculosis in paresis and other forms of insanity. In his study he made no use of the many thousands of clinical records, as they might affect his results and make them unreliable. Nontuberculous pulmonary complications are very common in general paresis and cannot always be distinguished from pulmonary phthisis. On the other hand, tuberculosis among the insane is often overlooked. Rosanoff thinks, however, that the number of pathological records on which his statistics are based is sufficiently large to establish almost beyond doubt the existence of a distinctly heightened immunity of paretics against tuberculosis. He asks to what this can be due and suggests that the immunity may be due to the same cause as that of former syphilis against syphilitic infection, the inflammatory reaction produced by both syphilis and tuberculosis being almost clinically identical. Paresis is generally acknowledged nowadays to be due to former syphilis, and Krafft-Ebing has shown that paretics are immune to syphilis. Other questions of practical interest suggest themselves. One of them is how would the course of a case of tuberculosis be affected by a superadded luetic infection?

Iridotomy.—J. L. Ziegler reviews the history of iridotomy since the days of Cheselden, its originator, showing how the pendulum of surgical preference has oscillated between the knife-needle and the scissors methods of operation, and points out the advantages of the knife-needle method in the case of incision, the lack of traction on the ciliary body, its freedom from postoperative inflammatory reaction, the avoidance of opening an eyeball that may contain fluid vitreous, the lessening of the tendency to iris hemorrhage from lowered tension, and in the avoidance of the nebulous scar that often follows a large corneal incision in old inflammatory eyes. Its disadvantages, he thinks, have been in the technique employed and in the imperfection of the instruments. The essentials for success in iridotomy by the knife-needle method are given by him as: (1) A good knife-needle, and he finds the modified Hayes instrument the best. Of course, it must have a well-sharpened point and edge. (2) A proper incision in the iris membrane; it should be a double incision. His choice is the V-shaped incision, which is undoubtedly the only one that will cut through all the iritic fibers in such a way as will give the greatest retraction of the membrane. (3) Absolutely no pressure shall be made in cutting with the knife-needle. This must be recognized as the main secret of success, whether the surgeon is cutting a dense felt-like iris membrane or a thin filmy capsule. With this rule observed there will be no traction on the ciliary body. (4) The knife-needle must be moved back and forth through the corneal puncture with a gentle sawing movement. (5) The corneal puncture and membrane counterpuncture must be far enough apart to make the corneal puncture a good fulcrum for the delicate leverage necessary in executing the iris incision. (6) The knife-needle must be so manipulated that no aqueous is lost, as this accident may prevent the completion of the operation and increase the tendency to iris hemorrhage by lowering the ocular tension. (7) Each incision must be a thoroughly clean cut, and all tearing of the tissues be avoided. (8) The most perfect

artificial illumination must be secured, either by an electric photophore of a condensing lens, as both iridotomy and capsulotomy require close and constant inspection of the operative field. Ziegler gives the details of the technique of his V-shaped iridotomy and reports cases. He also points out the applicability of the method to capsulotomy. He claims that it is by far the best way of incising a delicate secondary capsular cataract.

Hereditary Hypoplasia in Man.—C. P. Noble calls attention to the causes of degeneracy as affecting the race and as the basis of a number of morbid conditions. The impregnated ovum has within it potentially the whole future being and when it is defective the resulting offspring is abnormal. When the defect is very great we have monstrosities, idiocy, and imbecility. In a less degree it produces subnormal children, either mentally or physically, and between these, sharing in part in both, nervous instability. There is lack of sexual development, chlorosis, enteroptosis with all their complications and consequences, and he goes in considerable detail into the description of these. These patients are also peculiarly subject to tuberculosis and to puerperal infections, and should be carefully differentiated from those in whom the morbid condition is due to environment or other external or accidental causes. This explains the lack of results of treatment by routine gynecologists, who have not separated the cases, mental in origin, due to a defect primary in the ovum, from those cases in which the disease is acquired in normal or relatively normal individuals. As a young gynecologist Noble was puzzled by the cases of delayed development and it was pointed out to him by the late Dr. Harrison Allen that such patients were degenerates and their condition due to developed mental defects, but at that time they both thought that the trouble was primary in the nervous system and through the trophic nerve causing malnutrition and arrested growth. Now, however, Noble attributes it to a primarily developed mental defect. To distinguish such cases from those in which there is an acquired defect, we must learn the family history and search for the stigmata of degeneracy, especially the high-arched palate which is one of the most easily recognizable.

The Lancet, February 6, 1909.

Shell-fish Typhoid Fever.—H. C. Pattin refers to three well marked outbreaks of typhoid fever conveyed by cockles which occurred last year in Norwich, England. More than a dozen cases were traced to cockles obtained from two shops. The cockles which came from Ipswich were seized by the local health authorities, examined bacteriologically, and found to be grossly polluted with sewage.

Some Comparative Measurements of the Lives of Leucocytes When the Cells Are Resting in the Plasmata of Different Persons.—H. C. Ross has made these experiments with reference to the application of such measurements as an aid to diagnosis in infective diseases. His paper is mainly taken up with details of technique which must be read by those interested. The problem he set before him may be expressed thus: It appears reasonable to suppose that the plasma of a person suffering from an infective disease is poisonous to the leucocytes of a healthy person. This granted, the same plasma would not be so poisonous to the leucocytes of another person suffering from the same disease, because, presumably the cells would already be used to, or immune against, the toxin. Moreover, if the toxin of one infective disease differs from that of another, it may be believed that the immunity on the part of a leucocyte against one disease will not render it immune against another. Consequently, if it is possible to tell with accuracy when a leucocyte is dead, it will also become possible to measure the lengths of the lives of the cells after removal from the body. This in turn will enable us to make comparative measurements of the lives of leucocytes when they are mixed with the lives of different persons. Supposing that it is true that an infected plasma shortens the lives of a healthy person's leucocytes, but not those of another person with the same disease, it may be useful to reverse the process and assist in the diagnosis of infectious disease by making measurements of the lives of such a person's leucocytes when they are mixed with different plasmata. For instance, if the leucocytes of a person suffering from an indefinite infectious disease are found to be easily killed by the plasmata of persons suffering from a variety of diseases, but are not comparatively easily killed by the plasma of a person with, say, typhoid fever, the presumption would be that the given patient has, or has recently had, the latter disease, because his leucocytes are used to, or immune against, that particular infection. The author's observations are yet too few to enable him to draw positive conclusions.

Blood Crisis in Lardaceous Disease.—T. S. Kerr and E. I. Spriggs report the case of a man of 30 years admitted to hospital with fever, chest and abdominal pain, vomiting, and very dark colored urine. The case was thought at first to be one of appendicitis. The blood contained an extraordinary nucleated red blood cells. In a few days the urine cleared, and on quinine dosage the fever disappeared. Later violent diarrhea, with vomiting and abdominal distention, set in, with thrombosis of the superficial leg veins. The patient fell into a state of asthenia and died in about six weeks. Autopsy led to a diagnosis of lardaceous disease following syphilis, complicated by hemorrhages from the liver and bowels, with patches of old perihepatitis deforming the liver. The author comments on the fact of the blood crisis with reference to (1) the enormous number of nucleated red cells, (2) the rapid increase of the normal red cells and the hemoglobin from the anemia noted when the patient was first seen, and (3) the rapidity with which the nucleated cells disappeared. Bleeding from the kidneys is an uncommon symptom in lardaceous disease.

Early Cardiac Inadequacy.—Leonard Williams calls attention to the early signs and symptoms of failing circulation, dwelling especially on dyspnea, palpitation, tachycardia, and slight edema. The latter symptom, he says, may be due to ingestion of too much common salt. In health any salt excess is immediately eliminated by the urine. In certain abnormal conditions the chlorides are stored up in the blood, but are immediately passed off into the lymph spaces, where they attract to themselves sufficient water to make a solution isotomic with the blood plasma. A "normal saline," in fact, and edema is set up. Consequently an essential feature of all treatment is the restriction of the salt intake. Not more than 110 grains should be taken in 24 hours. We should determine first of all whether the hyposystate originates in the heart itself or in the arteries when the heart is working against an increased peripheral burden. We should lessen the latter by removing the vasoconstrictor toxins which are accumulating in the blood. Dietetic and hygienic measures rather than drugs will yield the best results. If the primary fault is in the cardiac muscle, rest in bed with cardiac tonics and diuretics, is all-important. But more important still in both sets of cases is that the patient should maintain an equable temperament and a calm mind.

British Medical Journal, February 6, 1909.

Iodine for Sterilization of the Skin of Operation Areas.—F. J. W. Porter commends the use of iodine for the purpose named. The evening previous to operation the skin area has a hot soap bath, but excessive scrubbing is not permitted. The skin is then shaved and a bandage of dry lint laid on. When the operation is about to begin, the area is freely painted with a ten per cent. spirituous solution of iodine and eucaine injected, if a local anesthetic is used. A fresh application is made just as the primary incision is to be begun. In case of a general anesthetic the painting is first made before anesthesia is begun and secondly when the patient is ready. Scrubbing is not permitted for the following reason: Epidermis is not an absolutely compact tissue. The cells are loosely packed and intercellular spaces exist, communicating with the outer air by microscopical clefts. These latter contain fat, bacteria, and sweat, all of which are readily dissolved out by the iodine solution, but if they are scrubbed, the hot water is apt to cause a swelling of the cells and the contents of the clefts may become stopped up in them. After the operation is finished the line of sutures is also painted. The author has followed the above plan in thirty operations, including appendectomy, radical cures for hernia, varicocele, hammer-toe, etc. His results have been just as good as with more elaborate methods of skin sterilization.

Atrophic Rhinitis Complicated by Mastoid Abscess and Extra Dural Abscess.—F. Stoker reports the case of a woman of thirty years who had had atrophic rhinitis for twelve years and had been variously treated without benefit. When first seen she was complaining of severe pain over the frontal and mastoid areas. In the course

of two days it became necessary to open the mastoid antrum in which thick yellow pus was found. There was considerable caries of the bone and the lateral sinus was exposed. She did well for a week when facial paralysis was noticed and there was severe pain over the side of the head and tenderness over the squamous area. It was considered necessary to operate further and an abscess was found under the dura from which pus escaped. She died quietly on the fifth day thereafter. No autopsy was obtained. The author says that infection had evidently passed from the nasopharynx to the middle ear and destroyed the ossicles and had also invaded the antrum and rarefied the mastoid bone. No symptoms occurred until the aditus became blocked with inflammatory products—granulation tissue or swollen mucosa—as until then a road for the inflammatory products was open into the nasopharynx. When the block occurred the symptoms appeared as the result of tension. The author adds that it would have been better to explore the middle fossa as well as the lateral sinus at the time of first operation. He also suggests that a more effective route for draining the floor of the middle fossa might be obtained where the complete mastoid operation is done, if the infero-lateral opening usually made is continued and forward by removal of the roofs of the external meatus middle-ear attic and antrum. The external semicircular canal would not be in danger if a bent probe was kept over it and the others could be safeguarded by cutting inward and forward.

Edema with Resolution by Urinary Crisis.—The patient of H. D. Rolleston and F. L. Golla was a man of twenty-seven years of age with chronic parenchymatous nephritis. When admitted to hospital he had edema of the legs and lower abdomen and thrombophlebitis of the left femoral vein. He remained under hospital care for some two months with the usual variation of symptoms, but eliminative measures failed to make any definite impression on the edema. Suddenly the amount of urine excreted daily rose from 48 oz. to a very much greater amount, on one day reaching 204 oz. In the course of four days he lost nearly 60 pounds in weight from the subsidence of the edema. After this sudden "urinary crisis" he had some slight headache and felt weak but was not thirsty. As to the cause of onset of this sudden renal activity the authors make no suggestions. They add some remarks on current theories as to the etiology of edema. In such a case as the one described, it is obviously of great importance, in order to secure accuracy, that there should be records of the elimination of the nitrogen and salts both before and during the crisis.

Berliner klinische Wochenschrift, January 25, 1909.

Roentgen Rays in Therapeutics.—Müller says that the advantages of *x*-rays in therapeutics are twofold: in the first place, they are especially promising in their action in the case of some otherwise incurable diseases and of very disfiguring skin affections, and on the other hand their application is accompanied with no pain and extremely little discomfort to the patient. The rays are selective in their action, their effect upon the healthy skin in correct application being limited to the increase of the pigment in the deeper layers; in pathological conditions the rays lead to thrombosis of the smaller capillaries, to degenerations of the abnormal cells and in the endothelium of the blood-vessels and to the gradual diminution of the diseased tissues by the interfering with their nutrition. Among the diseases most favorably affected by the rays is sycosis, both simple and parasitic; Müller does not remember a single case of this affection that was not cured or at least very markedly improved by the rays. Folliculitis, acne vulgaris, favus, trichophytosis, hypertrichosis, eczema, lupus, rodent ulcer, and, finally, some superficial malignant tumors are open to the influence of the rays. Still more important are the results obtained in the treatment of blood diseases such as leukemia, as well as in the obscure group gathered under the name "pseudoleukemia"—which are very obstinate under any treatment and many cases of which show improvement as soon as the *x*-rays are used; final cures have not been obtained, however, in these conditions by any means at our command.

Münchener medizinische Wochenschrift, January 26, 1909.

Marmorek's Serum.—Schenker says that Marmorek's serum has an antitoxic action in the human organism, and works especially well in pulmonary tuberculosis of the first and second grade, as well as in tubercular disease of the bones, the peritoneum, the kidneys, and the bladder. In more advanced stages of pulmonary phthisis the serum is often capable of stopping the progress of the disease and improve the general condition of the patient. The secret of success in such cases, however, lies in the persistence in the use of the serum, for the more obstinate and chronic is the process the longer is the treatment called for. In cases where large areas of tissue have been destroyed the serum is, of course, as little useful as any other possible procedure. The serum may be administered by the mouth or by the rectum, and has been shown to exercise no untoward action whatever. During its use general hygienic and dietetic measures used in treating tubercular infection must not be neglected, plenty of fresh air and sunlight affecting very much the rapidity of the improvement. Schenker concludes that Marmorek's serum is the best means for fighting tuberculous infection that is known to the medical profession at the present time.

Pyocyanase in Diphtheria.—Grósz has used pyocyanase in the gravest forms of diphtheria and reports very favorable results. The best results were obtained by spraying the solution into the pharynx and even the larynx, for which purpose a special apparatus had to be constructed. In other cases inhalation of steam saturated with pyocyanase was tried. In all cases the pseudomembrane disappeared very much more quickly than is usual in diphtheria, and the comfort of the patients was much increased. The temperature fell much more rapidly than with the use of antitoxin alone, and all general toxic symptoms were very favorably affected. In several severe cases of croup intubation was made unnecessary, the pyocyanase helping to separate the membrane very effectually; where intubation was done the tubes could be removed in much shorter time than has been usual. The author concludes that the use of pyocyanase deserves to become universal in cases of diphtheria, as it offers the best means of attacking the local lesions of the disease and shortening its course.

Deutsche medizinische Wochenschrift, January 28, 1909.

The Leucocytes in the Urine in Genitourinary Tuberculosis.—Goldberg says that he has noted very many irregularities in the shape of pus cells that appear in the urine in cases of tuberculous infection of the genitourinary tract. Colombino has laid special stress on such deformities, claiming that they appear in tuberculous disease in connection with the loss of the usual staining properties and the appearance of vacuoles in the protoplasm. Goldberg agrees that these appearances are almost constantly present in tuberculous disease, but his experience with gonorrheal cystitis proves that deformed leucocytes may appear in the urine in this affection. If gonorrheal infection can be positively excluded, the finding of deformed leucocytes in the urine is a valuable point in directing attention toward tubercular infection of the genitourinary tract. In the presence of gonorrhea the findings are of no value for differential diagnosis.

Unilateral Chyluria.—Salle reports the case of a man, twenty-five years old, who suffered from pain in the region of the left kidney, the affection being accompanied by the intermittent appearance of chylous urine. The chyle-content of the urine varied with the time of day, being much more considerable in the night; it also varied with the position of the patient, being increased when the patient was kept quiet in bed. That the diet had influence upon the appearance of the chyle in the urine was shown by the increase of fat in the urine when the fats in the diet were increased; the passage of the fat into the urine was proved by the demonstration of cod liver oil in the urine soon after it was administered to the patient. Cystoscopic examination showed that the chylous urine was secreted only from the left ureter. No casts were found. Salle concludes that these findings exclude the supposition that the metabolism was at fault in this case or that the secretion of the left kidney was abnormal. The explanation of the chyluria was probably due to some anatomical lesion of the lymph channels in the neighborhood of the left kidney.

Puerperal Abscess of the Uterus.—Anderodias and Pery give puerperal abscess of the uterus as a rare and not easily diagnosticated complication of puerperal infection. It occurs in the second week of the puerperium after the acute symptoms of sepsis have passed over. There is a rise of temperature of septic character. When the adnexa are not involved there is not much to be learned by bimanual palpation unless there is found tenderness and elasticity at one horn of the uterus. Generally the diagnosis is made at operation. If there is a single abscess not too large laparotomy may be done and the abscess opened and drained. When there are multiple abscesses hysterectomy becomes necessary. When no operation is undertaken the case is fatal.—*Journal de Médecine de Bordeaux.*

Book Reviews.

Surgery of the Ureter. An Historical Review (1585-1905) by Benjamin Merrill Ricketts, Ph.B., M.D., LL.D.; Member American Medical Association; Western Surgical and Gynecological Association; International Medical Congress, 1887; International Association of Railway Surgeons; Mississippi Valley Medical Association; Cincinnati Academy of Medicine; Ohio State Medical Society; American Proctologic Society; Honorary Member Society State of New York; Honorary Member St. Louis Medical Society; Fellow New York State Medical Association; Member Société Internationale de Chirurgie; American Urological Association, and Pan-American Congress. Cincinnati: 1908.

Industry of a most exceptional character is shown in this book. It bears evidence of a surprising amount of literary research on the ureter, and evidences that the author has provided what probably is the most exhaustive list thereof extant. The book was originally published as a serial in the *St. Louis Medical Review*, and is now presented by the author in a bound volume, rendering its contents accessible to whoever may need the immense material it contains. The usefulness of the work would have been materially enhanced for rapid reference had the author added an alphabetical index to the classification of his matter. Still, considering the vast amount of work devoted to the literature of the ureter by the author, it may not be asking too much to ask of the reader to search the titles presented for precisely the division of the subject-matter that he may need. It is doubtful whether anything has been written on the ureter within the four centuries covered that has not been at least mentioned by the author. A bibliographic appendix gives the titles of 249 of the author's own contributions to literature, and of two books he has in preparation. His subjects are extraordinarily varied. Selected at random the following titles manifest his industry: Construction of Sewers, Psoriasis, Oidium Albicans, The Relation of the Red Corpuscles to the Brain, External Urethrotomy, Plasto-Cosmetics in Surgery of the Face, Cremation, General Alopecia, The Surgery of Cleft Palate, Niagara's Water Power, Radical Operation for Prolapsed Rectum, Hematoma of the Ovary, Trigeminal Neuralgia, Protracted Birth of Second Intrauterine Twin.

Le Traitement Pratique de la Tuberculose Pulmonaire. Sept conférences faites à l'Hôpital de la Pitié. Par le Dr. Louis Renon, Professeur Agrégé à la Faculté de Paris; Médecin de la Pitié; Membre de la Société de Biologie; Membre de la Société d'Etudes Scientifiques sur la Tuberculose. Paris: Masson et Cie, 1908.

At the request of his colleagues the author has published these seven lessons which were originally delivered at the Hôpital de la Pitié. They are eminently practical and express the ideas of a keen observer at the bedside. Without being a sceptic he nevertheless points out the value of the newer and multitudinous methods of treating this disease as being largely of pshychotherapeutic value, and praises them as such. In a very sane way he goes into the diet, climatotherapy, hygiene, medicinal and symptomatic remedies, and includes such methods as are of value in the associated conditions such as diabetes, syphilis, emphysema, etc. Above all, the author insists upon doing no harm, on avoiding the rekindling of the latent fires of a quiescent phthisis, and on laying main stress upon hygienic methods without ignoring other remedies so long as they do not add to the burdens of the disease. As an exposition of the conservative methods of modern France these lectures are of distinct value.

Principles and Practice of Physical Diagnosis. By John C. Da Costa, Jr., M.D.; Associate in Clinical Medicine, Jefferson Medical College; Chief of Medical Clinic and Assistant Visiting Physician, Jefferson Hospital; Hematologist, German Hospital; Fellow of the College of Physicians of Philadelphia; Associate Member of the Association of American Physicians; Member of the American Climatological Association. With 212 original illustrations. Philadelphia and London: W. B. Saunders Company, 1908.

The work before us is a very useful book, particularly to the more thoughtful students of medicine, who inquire into the reasons back of physical phenomena. The author takes pains to describe such clinical anatomy as would have a practical bearing on the subject under discussion and to demonstrate the relations existing between pathology or physiology and the physical signs appropriate for each.

The technical methods employed in eliciting the various objective data are carefully explained and conservatively estimated, just and proportionate value being given to the useful and fanciful, showing the hand of the author as a clinician and teacher with practical experience.

The book is divided into sections, the first of which deals with the technique of physical examination, the second with the thorax, and the third with the bronchopulmonary system. The fourth section takes up the diseases of the bronchopulmonary system and the mediastinum. The fifth and sixth describe the heart and vessel diseases, while the last section has to do with abdominal signs.

The examination by means of Roentgen rays is noticed here and there, but only when of special value. The newer tuberculin reactions are included, as also are such of the more recent physical signs, as Grocco's paravertebral triangle, which has been under trial long enough to have its merits and limitations fully recognized.

Useful illustrations abound in the book, these being diagrammatic, clinical, topographical as the circumstances demand. As a whole, the work is clear, concise, interesting, and accurate, and may be used as a safe and sane guide in modern methods of physical diagnosis.

Pulmonary Tuberculosis and Its Complications. By Sherman G. Bonney, M.D., Professor of Medicine, Denver and Gross College of Medicine, Denver. Philadelphia and London: W. B. Saunders Company, 1908.

The volume before us represents an enormous clinical experience, such as is not apt to come to the average practitioner in large cities who has rarely had the advantage which the author has enjoyed of residing in a place where phthisical patients are apt to congregate, and yet where a general practice is at hand to keep one from being too narrow and to define less often many obscure cases as certainly tuberculous. The author writes from the practical and clinical standpoint. The tinge of the laboratory does not color his pictures except when it is of proved value and more than a mere theory. His case histories are to the point and help in elucidating his ideas. Perhaps the chief criticism against the work is that it is written for busy general practitioners, yet gives nearly eight hundred pages of text. The illustrations, colored, *x*-ray, and diagrammatic, are well chosen and add to the value of a very excellent volume. Under diagnosis there appear many helpful hints and the author advocates the use of the newer reactions, such as those of Calmette and v. Pirquet, as being of help in doubtful cases. But the strongest parts of the book deal especially with the older and well-tried methods, such as percussion, auscultation, history taking, and close observation of the course of the disease toward either cure or death. Recognizing the fact that the lungs are not the only organs involved, the writer goes into the complications such as are frequent in a pulmonary case. The physician in charge of lung tuberculosis must be on the lookout for the disease elsewhere and understand its management. Hence these adventitious manifestations occupy over one hundred pages of the text. Also associated conditions like syphilis, pregnancy, etc., receive due consideration. Under treatment the author shows himself a strong advocate of climate added to a carefully controlled hygiene. He appreciates that the individual must be considered primarily and that no stereotyped method is applicable to all cases. He decries the use of drugs.

Taber's Pocket Encyclopedic Medical Dictionary. Edited by Clarence W. Taber, Author of "Taber's Medical Dictionary for Nurses," "The Secret of Sex," Co-author of "Eales' and Taber's Anatomical and Physiological Chart," Associate Editor, Nicholas Senn, M.D., Ph.D., LL.D., C.M., Professor of Surgery, University of Chicago; Professor and Head of the Surgical Department, Rush Medical College, etc. Chicago: C. W. Taber, publisher.

This book might be useful in a way if it were not for its mistakes in spelling, derivation, pronunciation, and definition, and its careless proofreading. Such misprints as milearia, muscularis mycosal, mycosis grannloma, marrow, myllocele, myllomeningitis, idiophatic muscular atrophy, hygenic, mycosis tonic of blood (!), etc., disfigure nearly every page. As specimens of etymology we find: mogiphonia, from Gr *mogus*, hardly: migraine, from Gr. *half-head*; wound, *As Winnan Strive* (!); wrist, *As Writhin twist*, mons Veneris, L. *venereus*, Venus; peroneal, Gr. *piero*, pierce. Among the definitions, we note: muscle, "contractile tissues made up of bundles of fibers which serve as the means of motion"; molecular, "action through the physical elements of a substance"; melanin, "certain black pigments of the body"; malaria, "a disease due to air or water contaminated by poison from the soil" (!) The book was apparently written in the present century

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held December 24, 1908.

DR. WM. S. STONE IN THE CHAIR.

Carcinomatous Ulcer of the Vagina.—Dr. S. W. BANDLER reported a case of large carcinomatous ulcer of the upper part of the vagina. This was the fourth case of vaginal carcinoma which he had had the opportunity of observing in the last two and a half years. The first two had been treated by injections of trypsin and amylopsin at the time when this method was extolled as efficacious in the treatment of carcinoma. The case reported was of interest because, just one year ago, Dr. Bandler had done a hysterectomy for persistent uterine bleeding due to fibrosis of the uterus. Unfortunately, the specimen could not be found in the laboratory, as it would have been of interest to discover perhaps some early malignant changes in the cervix or fundus. The history showed, however, that nothing of an abnormal nature was noted leading to this supposition; hence the case was reported as one of a primary carcinoma of the vagina developing within a year after the operation of hysterectomy.

Ovarian Sarcoma in a Young Girl.—Dr. S. W. BANDLER reported a case of sarcoma of the ovaries in a child eleven years old. She was admitted to the Beth Israel Hospital June 25. Six months before she had had an attack of influenza, associated with cough and pain in her bones. She was confined to her bed for one week. Five weeks before admission she complained of gradually increasing weakness and headaches. Some pain was experienced during digestion which prevented the taking of much food. These annoyances disappeared after a week, to recur within a week. Constipation was marked. Four weeks before admission, during the second gastric attack, severe frontal headaches came on. The patient felt hot at night and she had sweats. She felt chilly during the day, and had a definite chill almost daily. Simultaneously the abdomen began to increase in size, reaching its maximum distention within ten days and remaining so distended ever since. Pain had always been a marked symptom, being present almost constantly. Though she was nauseated at times, there was no vomiting, but the fullness in the epigastrium became marked even after the taking of only small quantities of food. A week before admission a dry, harsh cough became marked. Her complaints on admission were general weakness, lack of appetite, chills, sweats, pain in the abdomen, and distention of the abdomen, a complication of symptoms which suggested tuberculosis and tuberculous peritonitis. The axillary glands were enlarged. Her lungs, posteriorly and on both sides, showed dullness and flatness, with diminished breathing and voice. Her pulse was 110. The abdominal veins were prominent. The temperature varied between 100° and 104°. On July 2 rectal examination revealed a mass growing up out of the pelvis. On July 3 her chest was aspirated and a bloody fluid containing a large number of endothelial cells was obtained, but no tubercle bacilli were found. On July 9 she was again aspirated and the same fluid was obtained, showing a large number of endothelial cells, actively mitotic. On July 17 the circumference of the abdomen at the level of the umbilicus was thirty inches. On July 18 an axillary gland was removed and showed on examination no signs of malignancy. Operation was considered useless, but at the earnest solicitation of the family the abdomen was opened on July 23. A six-inch median incision was made two inches above and four inches below the umbilicus. When the peritoneal cavity was entered there was an escape under great pressure of a large amount of dark serum. The greater part of the pelvic and abdominal cavity was occluded by a large mass the size of a water melon, very irregular in outline and seemingly composed of a number of smaller masses. The tissue was friable, and large bits of it broke off under manipulation. The tumor was quite adherent, not vascular, of a grayish-white color, and necrotic in various areas. The right ovary was somewhat more distinct, with a surface somewhat smooth, and its color more white than the other areas of the growth. The pedicles of the mass were clamped and ligated with chromic gut, the tumor excised, and the bleeding points ligatured. The abdominal wound was closed, leaving three gauze strips for drainage. There was a continuous discharge of a serous fluid and of very large bits of necrotic tissue from this time forth. On August 8, the temperature varied between 101° and 104°, and the abdomen was rigid and tender, especially on the right side. On August 9, the rigidity was still marked and larger necrotic bits and more discharge were noted. On August 11, a tumor-like mass was felt on the right side extending from the pelvis to the lower angle of the wound. This was incised under cocaine and the peritoneal cavity entered. Numerous adhesions which attached the intestines and omentum were loosened and a large quantity of bloody fluid was drained. The wounds continued to discharge constantly. The temperature varied, the pulse became gradually more rapid and weak, and the child died on October 5 of exhaustion. The microscopical examination in the laboratory furnished a report of sarcoma of the ovaries.

Carcinoma of the Cecum.—Dr. S. W. BANDLER reported a case of carcinoma of the cecum. The patient was a woman, sixty-two years old, who was admitted to the hospital July 7. She had always been well, but for the past two years complained of pain in the lower abdominal region, especially on the left side; the pain was of a sharp sticking nature. There were no renal annoyances, the bowels were irregular, but there was no change in the character of the stools. No mass was noted. There had been no gastric symptoms. There was slight tenderness on the right side. On physical examination a small mass the size of an orange, tender on pressure, was found on the right side, on a level with McBurney's point, but nearer the median line. The case was admitted to the surgical division, but for some reason or other was transferred to the gynecological service. On casual examination the tumor mass was noted and was seemingly present in the abdominal wall. While in a lying position the patient was asked to lift herself up, by this manipulation contracting the abdominal walls. During this manipulation the tumor mass was made more distinct; hence the diagnosis of dermoid tumor of the abdominal wall was made. As a rule intraabdominal tumors became less distinct under this manipulation, but in this case, as was seen at operation, the tumor was so closely attached to the anterior abdominal wall that this method of diagnosing intraabdominal tumors from tumors in the abdominal wall led to error. An incision was made directly over the tumor and the mass was found to be about the size of a large orange, closely attached to the anterior abdominal wall. The adhesions over an area nearly as large as the palm of the hand were loosened and a large hard mass involving the ileocecal region was noted, resembling the appearance noted in lymphosarcoma. As more adhesions were loosened the entire ileocecal tumor was brought out into the abdominal wound and a diagnosis of carcinoma was readily made. The entire ileocecal region was resected, and the cut ends of the ileum and colon were inverted and closed, and then a lateral anastomosis was done. A small strip of rubber tissue was left in as a drain and the abdominal wound was closed. On the eighth day there was a slight discharge of fluid and fecal matter. The fistula gradually closed within a few

days and the patient left the hospital six weeks after operation. She was then sent to the country and had since gained at least fifteen pounds. The patient looked well, had suffered from no intestinal annoyances, with the exception of a slight attack of abdominal distention, and she had not yet reached the stage at which a recurrence of the growth would bring on a fatal termination.

Strangulated and Sloughing Fibroid Polypus of the Uterus.—Dr. L. J. Ladinski presented this specimen and reported the case. The patient was a woman, forty-six years old, who had been married twenty-two years and had six children, the last sixteen years ago. She had had five abortions within a period of four years, the last eight years ago. She was curretted fourteen years ago. Three years ago her menstrual period beeame lengthened from three to ten days. The flow was very profuse, and at times clots were expelled from the uterus. There was no pain and urination was normal. Three days prior to her admission to the hospital, nine days after her regular menstrual period, she began to have colicky pains in the abdomen and back; this increased in severity and assumed the character of expulsive labor pains. The discharge at first was bloody and then became yellowish, very profuse, and of a foul odor. On September 24, 1908, she was admitted to the hospital. The vaginal examination revealed a large sloughing mass protruding from the dilated cervix into the vagina, and filling the pelvis completely. At operation the tumor could not be removed in mass because of its size; it could not be delivered at the vulvar outlet, for traction on the mass with forceps caused it to break down. The lower portion of the mass in the vagina consisted of degenerated blood clots and sloughing tissue. The tumor therefore had to be removed by morcellation until its base was reached, which was attached to about one-half of the entire length of the anterior uterine wall. The mass was separated with scissors. The uterine cavity was curetted, irrigated and packed with iodoform gauze. The tumor removed was a fibromyoma in a state of acute and subacute inflammation. A very slow recovery followed, the patient being discharged cured on December 5. This case emphasized the possibility of a submucous fibroid becoming strangulated. This fact, Dr. Ladinski said, should be taken as an additional indication for the operative treatment of fibroids.

Dermoid Cyst of the Ovary Perforating the Wall of the Sigmoid.—Dr. L. J. Ladinski presented this specimen and reported the case. The patient was a woman, twenty-nine years old, married ten years and had never been pregnant. Her menstrual history was negative, except for dysmenorrhea. For the past ten years she suffered from pain in both ovarian regions. She was curetted three years ago. Six months prior to admission to the hospital she was confined to her bed because of the pain in the lower abdomen, especially on the left side. Urination was frequent and painful. She was constipated and had pain with defecation. She was admitted to the hospital on May 8, 1908. The vaginal examination revealed an antiflexed small uterus and cystic ovary on the left side. A preliminary curettage was done, and the abdomen was opened. The left ovary was found to be cystic and very intimately adherent to the bladder, coils of intestines, and especially to the sigmoid. With difficulty the adhesions were broken up, several small pockets of pus were entered, but it was not possible to separate the mass from the sigmoid, because the tumor penetrated the wall of the sigmoid and protruded into the lumen. Therefore the mass was excised and the intestinal wall sutured. The patient had a protracted convalescence and was discharged from the hospital with a small fecal fistula. The pathological report stated that the growth impinging on the intestine and springing from the ovary was a simple dermoid cyst, in which were hair follicles, sebaceous glands, sweat glands, etc. There was nothing present which was in any way suggestive of malignancy in the structure.

Tuboovarian Abscess with Interesting Complications. Dr. Leonard S. Rau reported the case of a woman, nineteen years old, married three years. She had had one child who was two years old. Her previous history was negative, except a mild attack of appendicitis, until December, 1907, when she acquired gonorrhea. For some days before Dr. Rau was asked to see her on February 28, 1908, she had complained of severe pain on the left side and she had some fever. The vaginal examination revealed a pelvic abscess which was opened through the cul-de-sac of Douglas, and a large quantity of foul smelling pus was evacuated. The cavity was washed out daily and drained. A pocket of pus formed and another incision was made on March 3. For several weeks she did very well, but on April 1 a very tender swelling appeared on the left side. On April 2 a tuboovarian abscess was found. The left tube and ovary were removed, as well as the appendix. The abdomen became filled with blood which he thought came from the large number of raw surfaces resulting from the breaking up of so many adhesions. Because of the patient's condition, he was compelled to pack the pelvis with gauze and close the abdomen. Two hours later he was hastily summoned and found the patient pulseless and the dressings saturated with blood. He immediately transfused the patient, and when the pulse rate was reduced to 120 he opened the abdomen and removed the packing. After a tedious search the source of bleeding was found to be two very small arteries which were located down in the bottom of the pelvis. Convalescence was rather slow but uneventful. About the beginning of last November the patient had very severe pains, dragging in character, and he again operated. He found the uterus, the right tube and ovary, and intestines all matted together. Having decided on doing a radical operation he bisected the uterus; then and not till then was he able to get out the tube and ovary. In his manipulation he unfortunately severed the right ureter. After removing the uterus, ovary and tube he did an end-to-end anastomosis of the divided ureter. The patient did remarkably well for a time, passing fifty ounces of urine a day, and he was congratulating himself on the result when, on the tenth day after the operation, she began to complain of severe pain and the temperature went to 102.4°. On November 29 he made an incision directly over a mass that had formed and came upon a sac the size of a well filled bladder, which when opened allowed a large quantity of urine to escape. The urine was mixed with some floculent matter. The sac was retroperitoneal. The sac was washed out and packed, and the wound left open. Large quantities of urine escaped and the dressings had to be changed frequently. As the quantity of urine diminished he introduced a tube which he connected to a bottle. The tube was left in and the wound was washed daily with a 10 per cent. aluminium acetate solution. After a few days the discharge became so small that the tube was removed. At present the wound was closing quickly. No urine escaped through it, and the patient was passing about thirty ounces of urine daily.

Dr. John O. Polak reported a case in which he unfortunately severed the right ureter in doing an hysterectomy. He did an end-to-end anastomosis. The patient did well for twelve days and then began to complain of pain and had some elevation of temperature. An incision was made and a large quantity of urine and pus evacuated from a sac. This was drained for a long time. Six months later she developed a pus kidney. This was the third case in which he had to remove a kidney after operation upon the ureters.

Election of Officers.—*Chairman*, Dr. John O. Polak; *Secretary*, Dr. Samuel M. Brickner.

Stated Meeting, Held January 28, 1909.

DR. J. O. POLAK IN THE CHAIR.

Large Multilocular Ovarian Cyst and a Submucous Sessile Fibroid Tumor Showing Marked Circulatory Disturbances.—Dr. A. BROTHERS presented this specimen. A hysterectomy was done at the same time that the tumor was removed. A middle-aged woman was referred to him January 15, 1909. Her chief complaint was of severe uterine hemorrhages. She had a large abdominal tumor on the right side which was intimately associated with a distinctly enlarged uterus. The gaping cervix admitted the index finger, which recognized a submucous sessile tumor which bled on being touched. A diagnosis of multiple fibroids was made. When the abdomen was opened a large, round multilocular cyst was seen and an enlarged uterus showing fibroid nodules on its surface. Both were removed, including both Fallopian tubes. The left ovary was normal and was left to prevent a too sudden onset of the menopause. Upon splitting open the uterus there was found on its wall a sessile submucous fibroid tumor the size of the closed fist. Its mucous covering was intensely congested suggesting a beginning sloughing process. The diagnosis was confirmed by the microscope. While the body of the tumor showed no structural change, the capsule and mucous covering were so intensely congested that it was apparently only a question of a short time when ulceration or sloughing would have ensued. There were two points of interest in this case. First, had this patient been subjected to curettage to control the bleedings, it seemed to him that this process would have expedited the sloughing and the life of the woman would have been jeopardized. Secondly, a feature of interest in connection with this case was the explanation of why a sessile submucous tumor should have such extreme circulatory disturbances as to threaten sloughing or gangrene, when there was no particular reason for it.

Dr. HERMAN L. COLLYER said it was not always possible to make a diagnosis of these cases before operating. Doing a curettage in this case would no doubt have been a serious thing, and he commended the doctor upon his judgment.

A Simple Method of More Easily Detecting Injuries of the Ureter During Operation.—Dr. HENRY DAWSON FURNISS said that the surest method of detecting the ureters during operation was to make them easily recognized by passing into the lumen a catheter or bougie; but many times this was impracticable, on account both of the conditions encountered, and of lack of experience on the part of the surgeon. The ureter might be cut, the cut portion inspected, and then there might be doubt as to its identity. It struck him as a good and simple idea to give these patients methylene blue in one grain doses three times in the twenty-four hours preceding the operation, or to inject into the gluteal muscles twenty minims of a four per cent. aqueous solution of indigo-carmine just before the anesthetic was started, or after the patient had lost consciousness. Should the ureter be cut, the colored urine would quickly stain the intraabdominal gauze pads, and give warning that the ureter had been injured. If the ureter was cut on the distal side of a clamp or ligature, he believed there would be enough coloring of its lumen to show.

Dr. A. BROTHERS said that the suggestions offered by Dr. Furniss were very ingenious. However, injuries to the ureter were very infrequent, and the dangers of injuring it during operation he believed had been exaggerated. In his operative work, covering a period of about fourteen years, he said he had injured the ureter but three times, twice when doing abdominal work, once when doing vaginal work.

Dr. HERMAN L. COLLYER thought the method referred to by Dr. Furniss was especially valuable in those cases with large fibroids of the uterus where the ureters were likely to be distorted.

Dr. HENRY DAWSON FURNISS said this method would not be of aid unless the lumen of the ureter was cut into. He recalled an autopsy performed by him some time ago in which case both ureters were ligated with catgut. He believed that had the patient lived one day longer recovery would have followed because the sutures were so softened that they were just about to give way and so the obstruction would have been overcome.

Sacral Suspension of the Uterus.—Dr. JOHN VAN DOREN YOUNG read this paper. In May, 1903, he read a paper before the Obstetrical Society (see MEDICAL RECORD, October 24, 1903) in which he called attention to the importance of the uterosacral ligaments in the support of the uterus. His experience since that time had served to strengthen his opinion as to their value as factors in the general scheme of uterine support. The broad ligaments on either side prevented lateral displacement and aided in uterine support. He believed that the broad ligaments were only secondarily supportive in their action in the erect position. The round ligaments acted as guy-ropes to the fundus when the bladder was full, when the patient was in the recumbent position, and also in the early months of pregnancy. They could not be considered from their normal course or position as at all supportive in the upright position. When the uterosacral ligaments were taken into consideration, their function, when the body was in the upright position, was particularly supportive. It was his opinion that any operation looking to the relief of retroversion, retroflexion, or either of these combined with prolapse, would fall short of giving the desired relief unless the elasticity and strength of the uterosacral ligaments were taken into consideration. The reason that almost every anterior operation, *i.e.* every operation on the fundus by fixation or suspension, or some form of round ligament operation or broad ligament operation, had had its strong supporters, was the fact that in a large percentage of these cases the uterosacral ligaments were not stretched beyond their elastic limit and, therefore, the operation which held the fundus forward would relieve the condition. If these ligaments were stretched beyond their elastic limit, any operation which held the fundus forward alone would fail. In following out any method of treatment for the relief of retroversion with prolapse, all indicated surgical procedures such as curettage, repair of the cervix, perineorrhaphy, anterior colporrhaphy and removal of hemorrhoids, must be performed as adjuncts to the operation prior to any intraabdominal work. When the abdomen was opened it was wise to investigate first the condition of the tubes and ovaries, and to do whatever work was necessary to these organs and at the same time break up all adhesions which bound the omentum, intestines, or adnexa to the body of the uterus. The patient should then be raised to the extreme Trendelenburg position, the intestines taken out of the pelvis and held above the brim of the true pelvis by pads soaked in physiological saline solution. Then with the contents of the pelvis brought fully into view the operation upon the uterosacral ligaments was performed. The operation consisted in a plication of the uterosacral ligaments, with careful suturing of the three folds made. The stitch should include all three layers of the ligament near its insertion, and both layers of the folded end. The reduplicated fold should be to the outer side of the shortened ligament. A stitch was placed, running through the three layers, beginning at the outer, through the middle and then the inner fold, at the point farthest from the uterine body. In placing these stitches too great importance could not be laid upon the necessity of including all three of the folds of the ligament. A sharp knife was then taken, and the peritoneal covering of the three folds was scarified. A

fine catgut suture overhanded these three layers from end to end of the reduplication. The operation was contraindicated in very stout people and where there was retroflexion of the uterus with little or no prolapse. It was of particular value in retroversion with prolapse and cystocele. The points of advantage in the operation were as follows: The supporting of the uterus in its normal position from the bony structure above; the body and especially the fundus were freely movable for all the functions of the body; it did not distort but reproduced the curve of Carus. In the event of pregnancy there was no possibility of dystocia.

Dr. A. Sturmdorf said that, judged from a purely technical standpoint. Dr. Young's procedure for securing uterine dorsosuspension by pleating the uterosacral folds intraabdominally must accomplish that object, if nothing else. The question was raised, would this operation restore not only the anatomical direction of the uterus, but also the normal physiological poise and mobility so essential to the functions of this organ? Dr. Young's theoretical contentions for attacking the uterosacral folds were based upon his observations that "the sacral attachments of these folds suspended the uterus from the highest point of the pelvis and these folds were usually redundant and lax in retroversions." With regard to the first contention, it seemed difficult from a mechanical point of view to concede greater importance to the suspension of the cervix by the uterosacral folds from the highest point than to the retention of the fundus by the round ligaments at the lowest point. With regard to the second contention, namely, the laxity or redundancy of the uterosacral folds, one could not escape the suspicion that Dr. Young's method attacked a result rather than the cause of the trouble, for it was an easily demonstrable fact that the uterosacral folds were ligaments in name only and not in function. They were in reality only peritoneal folds whose elastic and muscular elements had at the most only a microscopical existence; furthermore, they represented the weakest and most variable structural attachments of the uterus, as shown by the fact that they were the first to yield to the pull of the vulsellum. Uterine displacement represented abnormal uterine support and any corrective procedure must be based upon a clear conception of the mechanism of its normal support, of which the uterosacral folds presented only a single passive factor. In a paper read some time ago (Medical Record, April 1, 1905) he attempted to elucidate the present conceptions on this subject; he emphasized that all muscular and ligamentous uterine attachments, and especially those constituting the pelvic floor, served to support the uterus, not by virtue of their textural resistance to displacements, but by acting as movable and contractile planes that deflected the displacing force of intraabdominal pressure. Paradoxical as it might appear, both the maintenance and the disturbance of uterine equilibrium were the result of the same intraabdominal pressure under the influence of balanced or unbalanced deflection. The deflection might be misdirected by a change in the contours of the pelvic floor, acquired and congenital, or by the abnormal skeletal planes presented by the so-called "Glenard habitus" with its resulting general splanchnoptosis. To attempt the correction of a uterine deviation resulting from such a cause by pleating the uterosacral folds would not reflect credit on this method, and it followed that in a given case the etiological factors and their resultants must indicate the particular line of correction to be followed. No one method could possibly be applicable to all causes and cases. The armamentarium for the cure of retrodisplacements must include orthopedic, mechanical, surgical, and medical means; any or all the operations proposed might find their sphere of usefulness, when they had reached a clear and correct conception of the normal uterine support and based their corrective procedures on such knowledge.

Dr. Sidney D. Jacobson said that in using the vulsellum forceps, it was a matter of every day experience that, upon the withdrawal of the hooks from the uterine tissue at the completion of the operation, blood oozed from the little holes made by the instrument. Sometimes the hemorrhage was quite profuse, and frequently the time lost in checking the flow was considerable, and almost always it was annoying to the operator because it prolonged the time of operating. The same was true if a stout silk thread was passed through the uterus for purposes of traction. If the uterus happened to be abnormally softened by disease or pregnancy, it sometimes occurred that the organ was lacerated. To protect the patient from unnecessary loss of blood and traumatism, a very ingenious little instrument had been devised by Dr. Monae-Lesser called the uterine repositor. This was a jointed rod inserted within the cervical canal by way of the vagina and used as a lever. The uterus was thus elevated into the abdominal incision and held there by an assistant. Dr. Barrows used a steel instrument shaped somewhat like an obstetrical forceps, to hold the uterus forward. Dr. Jacobson used scissors-like forceps armed with two crescentic rubber-covered jaws, which when closed formed an elliptical ring. This enabled one to draw the uterus out of the pelvis and hold it forward at will. The little instrument did the work thoroughly, without injury to the soft parts, saved time, loss of blood, and annoyance, and he recommended it to the members of the profession.

SECTION ON PEDIATRICS.

Stated Meeting, Held January 14, 1909.

Dr. Eli Long in the Chair.

Adenoids in Children.—Dr. Rowland G. Freeman said that adenoid hypertrophy in children was very frequent in New York, and that indications of its presence usually appeared during the first year. It was very important that adenoids should be removed just as soon as they gave symptoms and before mouth breathing became a habit. There were certain symptoms which would call attention to this condition. Perhaps the earliest symptoms occurring during the first year were the snuffles and snoring, particularly occurring at night. In another class of cases there were the frequent colds occurring anywhere from three, four, five, or six weeks apart. Then again there was the paroxysmal cough, the attacks resembling very much those of whooping cough. Dr. Freeman reported a case of a child in an institution who had attacks of coughing occuring in paroxysms reminding one of those of whooping cough. These paroxysms were very severe and prolonged, and during them the child became quite cyanotic. The child was poorly nourished and emaciated. With the cough there was expulsion of whatever food had been taken. Upon a careful examination, adenoids of large size were found and the mother was told that they should be removed, although on account of its desperate condition the child might die during the operation. The operation was done in the morning without any anesthetic. This operation could be done during the first year without any anesthetic and without frightening the child. The use of anesthetics in children should be guarded, especially in those of lymphatic constitution; sudden death might occur in the latter. If an anesthetic were used nitrous oxide gas was preferable. After the removal of the adenoids in this case, relief of the cough was almost immediate. There was no more vomiting, and food was retained, and since the operation, performed on October 24, there had been a gain of three pounds.

Unusual Aspects of Influenza.—Dr. Josephine Hemenway reported these cases:

Case 1.—She was able to follow the course of the disease

in this case from the very onset, the child being an inmate in the Babies' Hospital. The child was small, weighing ten and a half pounds. The history of the feeding was unimportant. The child had never had any acute illness of any form prior to this. Two days before admission the mother stated that she noticed the child was coughing, was fretful and had an evening rise of temperature. The baby was treated as if he had an ordinary attack of bronchitis. On the sixth day the baby developed an otitis media, requiring an incision of both drum membranes. The temperature curve presented by Dr. Hemenway was quite remarkable and was the reason for reporting the case. It ranged for eleven days from 95° to 105°. During the entire time of the illness the child did not look very ill. The influenza bacillus was found in pure culture from the throat. The child did not look at all as one would expect, judging from the temperature curve. The ears were carefully examined and incisions into the drum membranes had to be resorted to at other times. The surgeon strongly suspected sinus thrombosis. The child, however, was treated in a simple way, chiefly with stimulation, and the temperature fell to normal on the twenty-third day of his illness. Seven days later the temperature rose again, but soon fell to normal and had remained normal ever since. The child made a good recovery. This case was apparently nothing but an attack of influenza, showing a remarkable temperature curve, and complicated with an otitis media.

Case 2.—This was a case of acute hemorrhagic nephritis, occurring in a child four years old, an inmate of the Babies' Hospital. The child had had many attacks of acute bronchitis; otherwise she apparently was well. She never had any contagious or infectious diseases. Last December the mother noticed that the child had an acute coryza, an enlargement of the lymph glands and a slight cough. The urine was coffee colored. The temperature ranged from 101° to 103°. The child appeared prostrated, but a careful examination revealed nothing but a slight bronchitis and a systolic murmur at the apex of the heart. The urine was scanty and blood colored, with a large amount of albumen and some granular casts, and a specific gravity of 1030. The cultures made from the throat showed the influenza bacillus. Cultures of this bacillus could not be recovered from the urine. For four days the child showed a temperature; then it gradually fell to normal and a slow recovery ensued. There was a practically clear urine. The child was able to leave the hospital one month after the onset of the symptoms and with an apparently normal urinary condition.

Dr. Charles Herrman, discussing the first case reported by Dr. Hemenway, said that influenza with marked remissions of temperature was not so extremely rare, and recently he had seen some cases of this nature. During an epidemic of influenza, if a child was presented with this peculiar type of temperature curve, he said he would be strongly inclined to the diagnosis of influenza.

A Case of Congenital Blue Baby.—Dr. William P. Northrup presented this case. The trouble with this child was a narrowing of the pulmonary artery and an incomplete septum ventriculorum. Dr. Northrup had seen about twelve such cases. From his personal experience he said that when a child was born blue, and remained blue, there was but one lesion present to cause it, a narrowing of the pulmonary artery, or the orifice leading to the conus arteriosus, with a narrowing of the septum ventriculorum. This was in accord with the statement made by Dr. Brodbent.

Dr. Rowland G. Freeman believed that all the men who had served as pathologists at the Foundling Hospital had been convinced of the wisdom of Dr. Northrup's teaching concerning the common lesion in congenital heart cases. He had at present a blue baby of three months, without any heart murmur. Dr. Morse of Boston reported having followed thirty-two such cases of congenital heart lesion, and several of the cases had heart murmurs which disappeared later in life. This seemed to indicate that they had recovered from the condition.

Congenital Pyloric Stenosis; Operation; Death.—Dr. Henry Dwight Chapin reported this case. The baby was first seen at the dispensary when two months old, and a diagnosis of pyloric stenosis was made. The baby was breast fed for three weeks after birth. The labor was normal. The child had projectile vomiting. One hour after each feeding the baby would vomit whatever food had been taken. She had six stools a day. The physical examination showed an enlarged abdomen, and the peristalsis was noted over the stomach. The child was fed with barley water, but vomited that. She was then given 3-6-1 and that was regurgitated. She then was given 2-6-1 but the regurgitation continued. After a large dose of bismuth an *x*-ray was taken; this showed on the plate a light color in the region of the stomach, but the organ could not accurately be mapped out. Dr. Putnam was called in and concurred in the diagnosis of pyloric stenosis. An operation was advised and Dr. Putnam did a gastroenterostomy. The child lived but a few hours after operation. The stomach was shown, together with slides. There was found an increase of connective tissue and infiltrating cells at the pyloric end of this organ.

Dr. Charles R. L. Putnam said the baby weighed only five and a half pounds at the time of operation and was extremely anemic and weak. They had tried to feed the child for three days, but the vomiting was persistent. He did a pyloroplasty operation. The stomach was found to be much distended with gas. A tumor presented at the pylorus. Dr. Putnam described the operation. In these cases of pyloric stenosis, Dr. Scudder of Boston believed in the operation of gastroenterostomy. Dr. Nicoll of Glasgow had had success in these cases in doing a submucous pyloroplasty. The best end results were obtained, on the whole, when the pylorus was left as nearly normal as possible.

Dr. Dennett said that he had seen during the last year three such cases of pyloric stenosis and in all the peristalsis was noted as going from left to right. There was no reverse peristalsis in these cases. Tumor was not felt at any time.

Dr. Putnam said that the tumor was felt only when the child was under ether.

Dr. Charles Herrman said that some authors had endeavored to differentiate sharply between cases of pyloric stenosis and pyloric spasm. The case described by Dr. Chapin showed how difficult this might be. At one time the bowels were loose, and no tumor was palpable until the patient was under the anesthesia at the time of operation.

Dr. Godfrey R. Pisek believed that by distending the stomach with a considerable amount of pabulum and endeavoring to get some of it through the stenosed orifice, some relief might be obtained. By getting some food through there would follow an increase in nutrition, thus increasing the child's chances. Further the method might possibly aid in making the diagnosis.

Dr. Eli Long said that because of the high mortality which attended these operations in infants, an early and exact diagnosis should be made before operation was considered.

A Case for Diagnosis.—Dr. Edward D. Fisher presented a boy, thirteen years of age. The father was healthy, but the mother had pulmonary tuberculosis. An older brother was ill at present with pulmonary tuberculosis. The patient was a premature child, born at the seventh or eighth month. When born he was very feeble, and weighed about two and a half pounds. For one month he was fed with a medicine dropper. After he was one

month old he gained flesh and strength rapidly. He had his first tooth when two years old, and was first able to sit up alone then. With each double tooth he had convulsions. He did not talk until he was five years old. At this age he had a mild attack of measles. Otherwise he was well up to seven years, although mentally deficient and undersized. Then he had scarlet fever, with convulsions, and was confined to his bed for about three months. After one convulsion of great severity he was blind for one week. At this time he complained of great pain in the back of his head at a point where the mother said she could feel a protrusion and throbbing. At this time the patient began to pass large amounts of urine, averaging nineteen pints daily, and to drink correspondingly large amounts of water. Otherwise he remained well up to last summer when he had one convulsion in the night. He was up and about the following morning, but complained of pain in the leg. The mother then noticed that he walked unsteadily, throwing the leg outward. During the past few months he had gained in flesh and strength, walked without assistance, which was an impossibility three months before. For the first time he went to school and seemed mentally brighter. Repeated examinations of the urine showed nothing abnormal except the large quantities of urine passed. An examination of the eyes showed a slight cloudiness of the optic disc. On examination there was noted nystagmus, intention tremor, a spastic gait, exaggerated reflexes, and a peculiar hesitating speech. The patient was very emotional, mentally deficient, and was poorly nourished. The diagnosis was cerebral diplegia. A possible diagnosis of mutiple sclerosis was suggested, but it should be remembered that while this disease did occur in children, it was comparatively rare, and Dr. Fisher said he never knew of a child who was born with that condition. In this case he thought that it was possible that the cerebral diplegia, followed by an attack of scarlet fever, had resulted in a multiple sclerosis. Another diagnosis possible was a basal growth near the floor of the fourth ventricle of tuberculous origin. This might explain the diplegia and the polyuria. It was interesting, Dr. Fisher remarked, to note that the child had lately developed mentally, which was opposed to the diagnosis of multiple sclerosis, which as was well known, was a progressive disease, marked by increasing mental weakness.

Dr. Alfred F. Hess said that some years ago he had seen a similar case, with the same kind of gait, staccato speech, and a backward mentality. After following the case for some time he asked a prominent neurologist to make an examination; this he did, but he refused to give any positive opinion regarding the nature of the disease, but thought it might be one of multiple sclerosis and cerebellar ataxia of the Marie type. The child had difficulty in walking, and especially in going up stairs. The child was of premature birth.

Dr. William Van Pelt Garretson said that the patient presented was seen at the Vanderbilt Clinic and there they concluded that it was a case of multiple sclerosis. The early history of the child was indicative of delayed development. There was a distinct pulsation, as the mother stated, not over the posterior fontanelle, however, but over the site of the torcular Herophili, where the bony covering was imperfect. There was some involvement, which still persisted, of the peroneal group of muscles of the right leg, noted after the convulsion during the attack of scarlet fever. Since the attack of scarlet fever the boy had developed the classical picture of multiple sclerosis, which occasionally occurred after severe infections. The examination of the fundus showed the characteristic eruscentic haziness which was frequently present in disseminated sclerosis. Nystagmus was also present. The syllabic-staccato-scanning speech, the very marked intentional tremor, and emotional instability were present. There was a spastic condition of the extremities and a very ataxic gait. Romberg's sign, very active patellar reflexes, ankle-clonus, and Babinski's sign were also present, but there were no sensory disturbances which represented the unmistakable symptoms pictured in multiple sclerosis. The polyuria, Dr. Garretson said, was to be explained by the irritation of the diabetic center in the medulla by a placque of sclerosis.

Miliary Tuberculosis.—Dr. Alfred F. Hess reported a case of miliary tuberculosis in which the tubercle bacillus was found in the blood, thus enabling him to make the diagnosis. He also found the tubercle bacillus in the cerebrospinal fluid, although there were no symptoms of meningitis. The child was three and a half years old. The family history was negative. He was one of five children. There was no hereditary disease. The past history was also negative. The patient was brought to the hospital on December 10 with the history that for three weeks he had had pain in the abdomen, elevated temperature, etc. There was no headache, vomiting, or other symptom. The boy appeared to be in fair condition. The physical examination showed some cyanosis. The boy was fairly well nourished. The respirations were 60, pulse 160, and the temperature ranged from 101° to 104°. The diagnosis then could not be made. Typhoid fever, however, was thought of. The Widal reaction was negative, while the diazo was positive. The blood count showed 3,000,000 red cells, and 65 per cent. hemoglobin; there were 7,600 leucocytes, and 65 per cent. polymorphonuclears. A positive diagnosis could not be made. There were some râles in the chest. On December 12, 2 c.c. of blood was taken from the finger. Smears were made from the sediment of the blood, and tubercle bacilli were found in them and a positive diagnosis made. A lumbar puncture was also done, 30 c.c. of the fluid being taken. In the smears he found no tubercle bacillus. The fluid was injected into a guinea-pig that was killed after twenty days; tubercle bacilli were found in the omentum and in the glands. In the sediment of the cerebrospinal fluid he later was able to get tubercle bacilli. No bacilli were found in the sputum nor in the stools. The patient was removed from the hospital and died on the day following. This case was of interest because of the finding of the tubercle bacillus in the blood. No sings of meningitis were present, but nevertheless the tubercle bacillus was found in the cerebrospinal fluid.

A Case of Infantile Paralysis Involving the Muscles of the Face and Extremities.—Dr. Henry W. Frauenthal presented a boy who was first seen at the age of fourteen months. He was at that time suffering from infantile paralysis which involved the muscles of both extremities as well as all the muscles of the right side of the face and right eye. The chief facts of interest in this case were that up to six months ago he could not close the right eye, and had no vision in that eye, and all the muscles on the right side of the face were paralyzed. Two physicians who examined him declared that he gave no positive reaction of total degeneration and that there was no hope for any improvement. However, under skilled massage, combined with the high frequency and sinusoidal electricity he had slowly improved and was able to close his eye completely and distinguish objects clearly with his right eye. The location and character of the lesion in the brain for these facial involvements was not known, and no autopsy had been obtainable. This case was interesting for the following reasons: (1) It was stated in all textbooks on anterior poliomyelitis that, if paralysis existed for six months or a year without improvement, none would take place under any form of treatment. (2) That when positive reaction of degeneration in the paralyzed muscles existed, there could be no hope for improvement or recovery.

SECTION ON GENITOURINARY SURGERY.

Stated Meeting, November 18, 1908.

Dr. MARTIN W. WARE, CHAIRMAN.

Encysted Calculus Removed from a Female Bladder.—Dr. H. N. VINEBERG reported a patient with cervicovesical fistula, operated on once or twice by the late Dr. Paul F. Mundé, who finally sutured the cervix uteri into the bladder, thus closing the fistula. The menstrual fluid was now diverted into the bladder. Following this she suffered severe dysmenorrhea with vesical irritation. Cystoscopy (Kelly method) revealed a thick calcerous incrustation matter encroaching on the trigonum where the cervix projected. Most of this deposit was removed with forceps, and the patient obtained relief, but temporarily only. In April, 1904, Dr. Vineberg did a supravaginal hysterectomy to arrest menstruation, so that with its cessation new calcerous incrustations would cease, but the relief was not as anticipated. Examination of the bladder revealed an area the size of a half-dollar, hard as flint, which could not be dislodged. Accordingly the vesical wound was drained. The suprapubic wound closed in about three weeks, and for several months the patient was relieved. The symptoms recurred, and cystoscopy disclosed new deposits of calcareous matter at the old site. On August 10, 1908, the base of the bladder was found infiltrated with a hard mass the size of a hen's egg. This was everted into the cavity of the bladder, and the projecting circumference was broken off with bone forceps; then the removal of the remainder was comparatively easy. The mucous surface of the bladder exposed was quite smooth, and presented a small polypoid fibroid which was snipped off with the scissors. Convalescence was uneventful; the bladder symptoms gradually improved, and in about two months the patient was practically cured.

Nephrectomy for Nephrolithiasis, Followed by Extraordinary Complications.—Dr. L. BOLTON BANGS reported this case. The man, fifty-three years old, came under observation first in November, 1907. For the past two years he had been treated for nervous indigestion, and pus was discovered in his urine. A radiograph by Dr. Cole showed a stone in the right kidney pelvis and a second stone in the right ureter, low down or near the bladder. The kidney, exposed on December 14, 1907, was so disorganized that nephrectomy was done. On account of the man's condition the removal of the ureteral stone was postponed. The patient left the hospital seventeen days after operation in fair general condition. On January 3 he had severe pain in the region of the left kidney; on the following day he was unable to void urine and the bladder was found empty. That evening his temperature, which had been normal, rose to 103°. Palpation disclosed a vague fulness, but the left kidney could not be distinctly palpated. Anuria persisted forty-eight hours, and on January 5, after consultation, the left kidney was exposed and incised; it was much enlarged, but no stone or other obstruction could be found. On the following morning ten ounces of bloody urine were withdrawn from the bladder, and the next day he voided normally thirty-six ounces of urine, and the urinary excretion was evidently reestablished. Subsequent to this the patient developed a prostatic abscess, which was opened after delay, owing to objections of the family to further operation. Later on, he developed a suppurative orchitis and funiculitis, all of which had to be incised, and also, still later, pus appeared in the original nephrectomy wound, which had been healed for several months. At this time the patient had pus coming from five different sinuses, including the site of the original nephrectomy wound over the left kidney. He steadily lost ground, and died on April 11, 1908. Reviewing the case carefully, Dr. Bangs said that in his opinion the unwarranted delay in permission to evacuate the prostate created sepsis, which the patient, in his enfeebled state and with one kidney, was unable to withstand.

Dr. F. TILDEN BROWN referred to the not infrequent occurrence of serious infection advancing a long way before subjective or objective symptoms manifested themselves when the prostate was the focus.

Dr. WARE suggested that the stone impacted low in the dead ureter was possibly the starting point of the infection.

Dr. WILHELM KARO of Berlin said that the failure of the left kidney to secrete urine, which came on about two or three weeks after the opposite kidney had been removed, was probably the reflex origin and due to the calculus that had been left behind in the right ureter. In a number of cases of reflex anuria reported by Apolendt, Casper, and others, the condition had been relieved by catheterization of the ureter. He himself had recently observed such cases of anuria due to stones in the kidneys, and cured the anuria by catheterization of the ureters. Therefore, he emphatically advised in all cases of anuria to perform this procedure, and said one was justified in performing a nephrotomy only when the catheterization of the ureters did not relieve the condition.

Dr. VINEBERG asked if reflex anuria from a stone in a dead ureter was common. He himself did not think it was.

Dr. F. TILDEN BROWN asked whether it was considered essential that stones left in a dead ureter should be removed. Were they generally looked upon as a source of danger? While the one in the case reported by Dr. Bangs might have acted as a foreign body and a focus of infection, personally, the speaker said, he would not have anticipated trouble from it.

Dr. VICTOR C. PEDERSEN mentioned the case of a classmate who had a suppurating kidney after measles. The kidney was operated on by Dr. McCosh. Several years later he underwent another operation, whose precise nature Dr. Pedersen did not know, and in the after-treatment he suffered attacks of anuria, with high temperature and almost maniacal symptoms. At the suggestion of Dr. Pedersen, an *x*-ray examination was made, and revealed a small calculus about the brim of the pelvis. The stone, which was in the dead ureter, as in the case reported by Dr. Bangs, was removed. There was no pus surrounding it, and yet it was apparently the source of severe anuria.

Dr. BROWN said the conditions in this case were not strictly analogous to those in the case reported by Dr. Bangs. The original operation done by Dr. McCosh was the evacuation of an immense abscess connected with the kidney, and in that case one had not to deal with a dead ureter.

Dr. JAMES PEDERSEN suggested that the position of a calculus, whether low down in the ureter or high up, might determine for or against the occurrence of reflex anuria.

Litholapaxy in a Woman of Advanced Years.—Dr. JAMES PEDERSEN reported the case of a woman eighty-two years old, first seen by him June 11, 1908, under the care of Dr. A. L. Robinson. During the previous January she fell and fractured a thigh. During her forced confinement in bed frequency of urination, with some tenesmus, developed. After her return to New York the symptoms increased so that intervention became imperative. Cystoscopy disclosed two vesical calculi of moderate size. After preliminary treatment, litholapaxy was performed under chloroform interrupted by a few drops of ether. The duration of the anesthesia was thirty minutes, and was well borne. The calculi proved to be mere

shells surrounding globules of mucus. Mere contact of the lithotrite crushed them, with the exception of one fragment. The bladder was completely evacuated. The operation gave the patient immediate comfort; she had neither pain nor tenesmus after it. Six days after the operation she became unconscious during the night and developed slight paralysis. From this seizure she recovered in large measure, but she had two subsequent attacks, the second proving fatal on July 21.

Dr. Vineberg suggested that the calculi might have been removed through the vagina under cocaine. That would have been even simpler than litholapaxy, and would have obviated the danger of a general anesthetic.

Infected Hydronephrosis, Characterized by Hematuria; Nephrectomy.—Dr. Martin W. Ware reported the case of a man twenty-seven years old who was referred to him for attacks of renal recurrent colic so severe as to call for morphine. This history dated back three years. At times the urine was slightly bloody. Examination revealed tenderness in the left kidney. Macroscopically the urine seemed normal, but microscopically it showed a few red blood cells. The cystoscope revealed nothing abnormal save a markedly injected trigone. Upon synchronous catheterization of the ureters, apparently perfectly normal urine drained from both sides for the first ten minutes, then that from the left became blood-tinged, and subsequently that from the opposite side also showed blood in smaller amount. Upon laboratory examination, both specimens were reported sterile. Following this ureteral catheterization, the hematuria persisted for three or four days. About ten days later, while in Dr. Ware's office, he had another severe attack of renal colic. The urine during this attack was clear, and microscopically showed nothing abnormal. The following morning he was passing blood which, upon cystoscopy, was seen trickling from the left ureter. He also had pain and tenderness referred to the left kidney region. Another *x*-ray was negative. An exploratory nephrotomy was then done. The kidney was enlarged, and showed evidences of extensive inflammation around it, with numerous adhesions. In order to deliver the organ it was necessary to resect the last rib. Its upper pole was disintegrated and very friable. Upon incision of the kidney there was a free gush of blood and turbid urine, which had apparently been pent up. The interior of the kidney was thoroughly explored, with negative results. A drainage tube was then introduced, and it was decided to await subsequent developments. At this time a nephrectomy was not deemed justifiable, particularly because of the fact that the previous double ureteral catheterization had shown blood coming from both sides, this raising the suspicion that both kidneys were involved. After a week's drainage the urine cleared up entirely. After an injection of indigo-carmine the characteristic colored urine appeared in the usual time on the right side, while on the other side there was no response whatever. The same was true of methylene blue. As the left kidney apparently did not functionate at all, it was again exposed, and on cutting through its upper pole a distended sac was found intertwined with an abnormal arrangement of blood vessels about which the ureter was suspended. A clamp was applied and left in situ for four days, when the nephrectomy was completed. The patient made an uneventful recovery, and since the operation his health had much improved. An examination of the removed kidney showed a nodule resembling a supernumerary kidney. The pathologist reported that the parenchyma showed signs of compression and recent inflammation. Tuberculosis was absolutely excluded.

Dr. F. Tilden Brown said the case shown by Dr. Ware demonstrated the inadvisability of leaving in the ureteral catheters when collecting specimens for a differentiating test between the urines and kidneys. This practice was usually resorted to by the examiner as a time or labor-saving measure, and to get needlessly large quantities, and on account of the duration of this procedure the danger of trauma to the ureter was very great, and might reasonably be expected to obscure the true condition, especially in cases where one was on the lookout for the source and cause of a mild hematuria. In the majority of cases it was better to demand more of the laboratory worker and less of the patient. In other words, the speaker believed it far preferable for the examiner to supervise the synchronous collection of only so much urine (10 c.c.) as was essential for a complete analysis. At its termination the examiner should take advantage of the opportunities afforded on withdrawing each catheter to satisfy himself by cystoscopic inspection that the catheter is being withdrawn from a ureter, and, secondly, to note any phenomena appearing at this moment.

Dr. Karo asked Dr. Ware why he had not examined the kidneys by the modern methods of functional examination. These methods enabled us to determine whether or not we were justified in performing a nephrectomy.

Healed Chancroid, with Extensive Ulceration.—Dr. George K. Swinburne showed this case. The man, twenty-six years old, consulted the speaker in November, 1906, for a chancroid of the glans eleven months old, during which he had been under constant treatment. All ordinary means had been used. One physician had employed daily injections in the buttock of a 2 per cent. solution of bichloride of mercury for thirty days for an underlying lues. During that time there had been a steady extension of the disease, comprising an extensive ulceration on the under surface and side of penis and glans; the urethra had been perforated, and the patient passed all of his urine through the wound. The constant pain was rendered worse on urination; so that he passed urine only twice in twenty-four hours. After a week of ineffectual treatment, Dr. Swinburne painted the surface with equal parts of ichthyol and an organic silver salt, first applying a cocaine solution. The application was made after urination, so that he could go as long as possible without removing the dressing. From that time pain diminished and the ulcer began to heal, at first rapidly, then more slowly. The applications were frequently repeated. The ulcer showed a tendency to break down at the angles when the applications were stopped, or when any other preparation was substituted. The ulceration finally healed entirely, but the urine still passed through the gap, and the patient was now anxious to have something done to repair the condition. Behind the false opening, in the spongy body and the corpora cavernosa, was a thick indurated mass which interfered with erection, the glans penis remaining soft. The patient had a chronic urethral discharge without gonococci. Dr. Swinburne said that his own advice was to let the condition alone or else amputate the penis behind the indurated mass.

A Case of Healed Chancroid, with Destructive Ulceration, of One Year's Duration.—Dr. Victor C. Pedersen reported the case of a man thirty years old, single, a chauffeur, first seen in the summer of 1907. About two weeks after illicit intercourse a painful sore appeared on the glans. A physician applied a wet bichloride dressing. In spite of this, rapid extension followed, and when Dr. Pedersen saw him the ulcer involved the foreskin and the meatus. Numerous pockets exuded pus. The depths and angles of the pockets were filled with a necrotic tissue of jelly-like consistence, closely resembling soft boiled cartilage. No definite organisms were in the pus, and Dr. F. M. Jeffries of the New York Polyclinic did not make a positive diagnosis as to the character of the slough. Part of it suggested syphilis, part tuberculosis. On September 12, 1907, under ether, the foreskin was divided,

the sinuses and pockets exposed, and the entire area cauterized with a weak solution of bromine water. All sloughing and edematous tissue was cut away as far as possible and a wet dressing of black wash applied. At the end of six days no great improvement had taken place, and it was then decided to cauterize the sloughs lightly with nitric and open the sinus passing around the urethra by a transverse incision at its base. This was done, and iodoform powder was then liberally applied. Five days after the cauterization a slough was cast, opening into the urethra. With the exception of this, the patient made an uneventful recovery, and excepting for the loss of the skin sheath of the penis, the only deformity of the organ occurred at the terminal part of the urethra, where the glans had been largely eaten away; here there was a peculiar doubling of the canal upon itself toward the left. The defect in the urethra caused by the slough still persisted. To repair this a plastic operation would be necessary.

Dr. BANGS said that during his service at the old Charity Hospital on Blackwell's Island these cases of extensive destruction of the various tissues of the penis were comparatively common, and his experience had taught him that in the course of time nature accommodated itself to the functions of the organ, and that it was not wise to attempt operative correction of the deformity too early. The speaker said he could confirm the observation of others that the use of mercury in these cases, internally, would light up the chancroidal ulceration and was apt to prolong the process of repair.

Dr. WARE suggested that thiosinamine might be employed in some of these cases, with the view of causing a disappearance of scar and granulation tissue.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

HUMAN FOODS. By HARRY SNYDER, B.S. 12mo, 362 pages; cloth; illustrated; $1.25. The Macmillan Co., New York.

MILITARY HYGIENE. By R. H. FIRTH, R.A.M.C. 299 pages, 12mo; cloth; illustrated. P. Blakiston's Sons & Co., Philadelphia, Pa.

BIBLIOTHÈQUE DE THÉRAPEUTIQUE. Publiée sous la direction de A. GILBERT et P. CARNOT. 12mo, 400 pages; cloth; illustrated. J. B. Baillière et Fils, Paris, France.

THE FUTURE OF MEDICINE. By SYDNEY W. MACILWAINE, M.R.C.S., L.R.C.P. 8vo, 44 pages. P. S. King & Son, London, England.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

WISCONSIN STATE BOARD OF MEDICAL EXAMINERS.

Milwaukee, January 12, 13, and 14, 1909.

ANATOMY.

1. Describe the external jugular vein.
2. Describe the sartorius muscle, giving its origin and insertion.
3. What is the cerebellum and where is it situated? What is its size as compared with the cerebrum? Describe the medulla oblongata.
4. Name all the cranial nerves and give their function.
5. Give the boundaries of the axillary space and name its contents.
6. Describe the portal circulation.
7. Name and give origin of the muscles of the posterior tibial region, superficial group.
8. Describe the pleura.

PEDIATRICS.

1. Give the definition, prophylaxis, and treatment of cretinism.
2. Give synonyms, symptoms, and treatment of spasmodic laryngitis.
3. Give synonym, etiology, symptoms, prognosis, and treatment of anterior poliomyelitis.
4. Give etiology and treatment of enuresis.

CHEMISTRY.

1. Define molecule, acid, base, and salt.
2. Give the chemical name and formula for the following substances: (*a*) silver nitrate, (*b*) acetic acid, (*c*) chalk, (*d*) green vitriol.
3. Give, by equations, the chemical reactions when the following substances are combined: (*a*) caustic potash and sulphuric acid; (*b*) sulphuric acid and manganese dioxide.
4. Name three compounds of carbon with oxygen and give their physical properties, explaining the dangerous effect of each on animal life.
5. Name NH_4HO and give some of its common uses.
6. Explain test for total acidity and for the free HCl in contents of stomach.
7. (*a*) Give common name of $CuHAsO_3$ and state its properties and uses. (*b*) What is the chemical composition of Schweinfurth green?
8. Define toxicology, corrosive, narcotic, ptomain.
9. Name five poisonous tinctures, with medicinal dose of each.
10. Describe in detail two reliable tests for albumin in the urine.
11. Describe three tests for the presence of sugar in the urine.

PRINCIPLES AND PRACTICE.

1. Give symptoms and differential diagnosis of gastric ulcer.
2. What are the causes of dilatation of the stomach?
3. Give diagnosis of acute endocarditis.
4. Give treatment of acute tonsillitis.
5. Give medical treatment of simple goiter.
6. Give etiology of acute bronchitis.
7. Give treatment of enterocolitis in children.

MATERIA MEDICA AND THERAPEUTICS.

1. Give the physiological actions of strychnine in poisonous doses and tell why it destroys life.
2. Name the agents affecting the organs of vision when locally applied. Describe, briefly, the actions on the eye of each.
3. What are the principal stimulating diuretics, with the doses of each?
4. What anthelmintics are used against the different intestinal parasites respectively?
5. What is hydrogen peroxide? What are its therapeutical uses?
6. What is the therapy of digitalis?

OBSTETRICS.

1. Name and describe the different stages of labor and your management in each stage.
2. What is the amniotic sac? Name its contents and tell what service it performs.
3. State the kind and proper use of anesthetics in normal labor.
4. How is delivery accomplished in a transverse presentation?

5. What condition of the membranes may complicate labor and render it difficult? Give treatment for condition you name.
6. What is the most common occurrence that may suddenly change a favorable condition of labor into a dangerous one? Give treatment for same.
7. What are the symptoms, prognosis, and treatment for inversion of the uterus?
8. What are the permanent changes in the female sexual organs following parturition?

GYNECOLOGY.

1. Give diagnosis, prognosis, and treatment of pelvic hematocele.
2. State the pathological and clinical features of ectopic gestation.
3. Name the physiological movement of the uterus and the forces by which it is sustained.
4. Give deviations of uterus from the normal position and give treatment for prolapse.

GENERAL SURGERY.

1. What is your treatment of severed arteries, tendons, and nerves, and of punctured wounds?
2. How would you treat a fractured patella?
3. What treatment would you use for the dislocation of the acromial end of the clavicle?
4. Describe the amputation of choice of a leg with a view of the most successful use of an artificial limb.
5. Describe your treatment of infections of the extremities, both local and general.
6. Describe cholecystitis and appendicitis and give the indications for surgical interference.
7. Differentiate malignant and non-malignant growths, and give indications for surgical interference.
8. What principles do you practise in the treatment of shock relative to interference by surgical procedure?

PHYSICAL DIAGNOSIS.

1. Give the physical signs of primary pulmonary tuberculosis.
2. Give the physical signs of pulmonary emboli.
3. Give the physical signs of acute cardiac dilatation.

HYGIENE.

1. What hygienic treatment would you prescribe for a surgical case involving protracted confinement?
2. What hygienic treatment would you prescribe for a case of beginning pulmonary tuberculosis?

NEUROLOGY.

1. What are nerves? Give chief divisions of the nervous system.
2. Through what openings do the cranial nerves find exit from the skull?
3. Describe the spinal cord and its membranes.
4. Give function of white and gray matter.
5. Explain reflex action.
6. Give pathology of infantile paralysis.

DIETETICS.

1. What special use does each one of the following serve the body after ingestion: coffee, tea, alcohol, fats, carbohydrates, proteids?
2. Give hygienic and dietetic treatment of pulmonary tuberculosis.

MEDICAL JURISPRUDENCE.

1. Define (*a*) mania, (*b*) melancholia.
2. What is paranoia?

PHYSIOLOGY, OPHTHALMOLOGY, AND LARYNGOLOGY

1. Describe the pulmonary circulation and the changes which are produced in the blood by aëration.
2. Describe the normal heart sounds, give probable reasons for same, and tell where they are best heard.
3. Enumerate the functions of the spinal cord and its special centers.
4. What physiological process takes place in the capillaries?
5. What are the changes in bread during digestion, and where do each occur?
6. (*a*) Discuss inflammation. (*b*) What are the functions of the skin?
7. Give structure and function of the liver and kidneys.
8. Define myopia, presbyopia, hypermetropia, and astigmatism.
9. Differentiate glaucoma, iritis, and keratitis.
10. Explain the physiology of visual accommodation to light and distance.
11. Differentiate acute laryngitis and croup, and give treatment.
12. Give the etiology, symptoms, and treatment of tuberculous laryngitis.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

WISCONSIN STATE BOARD OF MEDICAL EXAMINERS.

Milwaukee, January 12, 13, and 14, 1909.

ANATOMY.

3. The *cerebellum* is that part of the encephalon which is situated beneath the occipital lobes of the cerebrum; it is located in the inferior occipital fossæ, and is separated from the cerebrum by the tentorium cerebelli.

The *cerebellum* is about 3½ to 4 inches transversely, 2 to 2½ inches anteroposteriorly, and about 2 inches thick in the center; it weighs about 5½ ounces, and its proportion to the cerebrum is about 1:8.

The *medulla oblongata* is the lowest part of the encephalon, and is continuous below with the spinal cord. It extends from the lower margin of the pons to the lower margin of the foramen magnum. It lies in the basilar groove of the occipital bone; its dorsal surface is between the cerebellar hemispheres. It forms the lower part of the floor of the fourth ventricle. It is about one inch long, half inch wide, and half inch thick. It has anterior and posterior median fissures, which are continuous with those of the spinal cord.

4. The special *names* by which the twelve pairs of nerves are generally known are: 1. Olfactory. 2. Optic. 3. Motor oculi. 4. Trochlear or Pathetic. 5. Trifacial. 6. Abducens. 7. Facial. 8. Auditory. 9. Glossopharyngeal. 10. Pneumogastric or Vagus. 11. Spinal Accessory. 12. Hypoglossal.

Functions: 1. Special sense of smell. 2. Special sense of sight. 3. Motor. 4. Motor. 5. General sensation and motor. 6. Motor. 7. Motor. 8. Special sense of hearing. 9. General sensation and special sense of taste. 10. Motor and general sensation. 11. Motor. 12. Motor.

5. The axilla is *bounded:* Anteriorly, by the clavicle, Subclavius, Pectoralis major, costocoracoid membrane, Pectoralis minor; *posteriorly*, by the Subscapularis, Teres major, and Latissimus dorsi; *internally*, by the first four ribs, first three Intercostal muscles, Serratus magnus; *externally*, by the humerus, Coracobrachialis, and Biceps.

Contents: Axillary vessels; brachial plexus of nerves, and branches; some branches of the upper intercostal nerves; lymphatic glands, fat, and loose areolar tissue.

7. The muscles of the superficial group of the posterior tibial region are: Soleus, Gastrocnemius, and Plantaris.

Soleus arises from: back of head of the fibula, and upper part of the posterior surface of shaft of fibula; from oblique line of tibia, and middle third of internal border of tibia.

Gastrocnemius arises from: the condyles of the femur and adjacent part of posterior surface of femur.

Plantaris arises from: posterior ligament of knee-joint, and ridge above the external condyle of femur.

CHEMISTRY.

1. A *molecule* is the smallest quantity of any substance which can exist in a free state.

An *Acid* is a compound of an electronegative element or radical with hydrogen, part or all of which hydrogen it can part with in exchange for an electropositive element, without the formation of a base.

A *Base* is a compound which on entering into double decomposition with an acid produces a salt and water.

A *Salt* is a substance derived from an acid when the hydrogen of the latter has been partially or completely replaced by an electropositive element or elements (a metal or metals).

2.

	CHEMICAL NAME.	FORMULA.
(*a*) Silver nitrate.	Silver nitrate.	$AgNO_3$
(*b*) Acetic acid.	Acetic acid.	CH_3COOH
(*c*) Chalk.	Calcium carbonate.	$CaCO_3$
(*d*) Green vitriol.	Ferrous sulphate	$FeSO_4$

3. (*a*) $2KOH + H_2SO_4 = K_2SO_4 + 2H_2O$.
(*b*) $2H_2SO_4 + 2MnO_2 = 2MnSO_4 + 2H_2O + O_2$.

4. There are only two compounds of carbon with oxygen:

(1) *Carbon monoxide*, CO, a colorless, tasteless gas, slightly soluble in water and in alcohol. It is exceedingly

poisonous, and when inhaled forms a very stable compound with the hemoglobin of the blood.

(2) *Carbon dioxide,* CO_2, a colorless, suffocating gas, with an acid taste; its solubility in water increases with the pressure. It is not poisonous, but produces death by reason of spasm of the glottis; it asphyxiates.

5. NH_4HO is ammonium hydroxide; it is used as a reagent in the laboratory, and also as a cardiac stimulant.

6. *Test for total acidity in the stomach contents:* Titrate 10 c.c. of gastric contents with decinormal sodium hydroxide solution, using phenol phthalein as an indicator. Each c.c. of the decinormal NaHO used corresponds to 0.00365 grammes of HCl. Therefore, the number of c.c. of decinormal NaHO used multiplied by 0.0365 gives the percentage of total acidity expressed in terms of HCl.

Test for free HCl in stomach contents: Add to a few drops of the filtered gastric juice one drop of a solution of dimethyl-amido-azo-benzol; a cherry-red color develops in the presence of free HCl.

7. (*a*) The common name of $CuHAsO_3$ is Scheele's green. It is a bright green powder, insoluble in water, but soluble in acids and also in ammonium hydroxide; it is very poisonous. It is used as a pigment, and as an exterminator of bugs, beetles, parasites, and fungi.

(*b*) The chemical composition of Schweinfurth green is $Cu(C_2H_3O_2)_2 + 3Cu(AsO_2)_2$.

8. *Toxicology* is that branch of medical science which appertains to poisons; it includes their character, origin, actions, symptoms produced, antidotes, treatment, and detection.

A *Corrosive* is a substance capable of producing death or serious harm by its chemical action upon a tissue with which it comes in direct contact.

A *Narcotic* is an agent which is capable of producing profound sleep; or of stupefying.

A *Ptomain* is a basic nitrogenous compound produced from protein material by the bacteria which produce putrefaction.

9.

FIVE POISONOUS TINCTURES.	MEDICINAL DOSE.
1. Tincture of aconite.....	♏vij
2. Tincture of nux vomica..	♏viij
3. Tincture of opium.....	♏viij
4. Tincture of iodin.....	♏jss
5. Tincture of strophanthus.	♏viij

10. *Two reliable tests for albumin in the urine:* "The urine must be perfectly clear. If not so, it is to be filtered, and if this does not render it transparent, it is to be treated with a few drops of magnesia mixture and again filtered."

I.—*The heat test:* "The reaction is first observed. If it be acid, the urine is simply heated to near the boiling point. If the urine be neutral or alkaline, it is rendered *faintly* acid by the addition of dilute acetic acid, and heated. If albumin be present, a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of HNO_3."

II.—*Heller's modification of the nitric acid test:* "Place in a test-tube a layer of HNO_3 about 2 centim. in thickness; then, with a pipette, carefully float upon the surface of this a layer of the urine in such a manner that the liquids do not mix. If albumin be present, a cloudy ring appears *at* the point of junction of the two layers, the borders of the cloud being sharply defined. A cloudy ring may be formed by the presence of an excess of urates, but in this case it is not *at*, but *above*, the point of junction of the layers, and its upper border is not sharply defined, but fades off gradually."—(Witthaus' *Essentials of Chemistry.*)

11. *Three tests for the presence of sugar in the urine:* The urine should first be tested for albumin. If this be present, it should be removed by heating the urine to near the boiling point, and filtering from the coagulum.

(1) *Fehling's test:* Place in a test-tube a few c.c. of the liquid prepared as stated below, and boil; no reddish tinge should be observable even after five minutes' repose. Add the liquid under examination gradually, and boil after each addition. In the presence of sugar a yellow or red precipitate is formed. In the presence of traces of glucose, only a small amount of precipitate is produced, which adheres to the glass, and is best seen when the blue liquid is poured out.

[The reagent must be kept in two solutions, which are to be mixed immediately before use. Solution I consists of 34.653 gms. of crystallized $CuSO_4$, dissolved in water to 500 c.c.; and solution II of 130 gms. of Rochelle salt dissolved in 500 c.c. in NaHO solution of sp. gr. 1.12. When required for use equal volumes of the two solutions are mixed, and the mixture diluted with four volumes of water.]

(2) *Fermentation test:* Three Smith's fermentation tubes are used, each containing a little compressed yeast, one filled with the liquid to be tested, the second with pure water, and the third with a dilute solution of glucose, and the three are put in a warm place over night. If gas collects in the first and third tubes, but not in the second, the liquid contains sugar; if gas collects in the third only it does not; under any other circumstances the yeast is at fault.

(3) *Boettger's test:* Render the urine strongly alkaline by addition of Na_2CO_3. Divide about 6 c.c. of the alkaline liquid in two test-tubes. To one test-tube add a very minute quantity of powdered subnitrate of bismuth, to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by a dark or black color of the bismuth powder, the litharge retaining its natural color.—(From Witthaus' *Essentials of Chemistry.*)

MATERIA MEDICA AND THERAPEUTICS.

1. In poisonous doses strychnine causes: asphyxia, tetanic spasms, opisthotonus, vomiting; the eyes are open, and fixed.

Death is due to asphyxia or to paralysis of the respiratory center.

2. *Agents which affect the organ of vision when locally applied.—Mydriatics* (dilate the pupil): Atropine, homatropine, daturine, hyoscyamine, coniine, cocaine; and probably gelsemine, muscarine, hydrocyanic acid, aconite, and amyl nitrite.

Myotics (contract the pupil): Pilocarpine, physostigmine, and probably nicotine.

Dilators of the pupils, especially atropine and homatropine, are used to dilate the pupil for ophthalmoscopic examination, and to prevent or break down adhesions of the iris. Contractors of the pupil, especially physostigmine, are used to overcome the effects of atropine, to prevent or break down adhesions of the iris, and to prevent too much light entering the eye in painful diseases of it.

Drugs which *impair or paralyze accommodation.*—Atropine, daturine, hyoscyamine, homatropine, cocaine, physostigmine, pilocarpine, gelsemine, and coniine.

Intraocular tension is increased by atropine (large doses), hyoscyamine, and daturine. It is decreased by cocaine, hyoscine, and physostigmine.

Gelsemine paralyzes the external ocular muscles especially the levator palpebræ and the external rectus, by its action on the terminal nerve filaments.

Cocaine, by stimulating the unstriped fibers in the orbital membrane and the eyelids, causes the eye to protrude. Coniine produces ptosis when given in large doses. (From White and Wilcox's *Materia Medica,* etc.)

3. *The principal stimulating diuretics, with dose,* are: Turpentine (oil of), ♏xx; juniper (spirit of), ʒj; buchu (fluid extract of), ♏xxx; cantharides (tincture of), ♏x; and alcohol.

4. ANTHELMINTICS. *For tape worm:* Filix mas; granatum; pepo; turpentine; kousso.

For thread worm: Alum, quassia, eucalyptol, tannin.

For round worm: Santonin; spigelia, chenopodium.

5. As used in materia medica and therapeutics, solution of hydrogen peroxide is an aqueous solution of H_2O_2, slightly acid, and containing when freshly prepared about ten volumes of available oxygen.

Its therapeutic uses are: disinfectant; for cleansing wounds, fistulæ, etc.; to absorb false membranes in diphtheria; sometimes for treatment of leucorrhea, or gonorrhea.

6. *Therapy of digitalis:* Digitalis is indicated in diseases of the heart, (1) when the heart action is rapid and feeble, with low arterial tension; (2) in mitral lesions when compensation has begun to fail; (3) in nonvalvular cardiac affections; (4) in irritable heart, due to nerve exhaustion. Digitalis is contraindicated in diseases of the heart (1) in aortic lesions when uncombined with mitral lesons; (2) when the heart action is strong, and arterial tension high.

Digitalis is also a diuretic; and it is also used in some forms of nephritis, exopthalmic goitre, pneumonia, chronic bronchitis, etc.

OBSTETRICS.

2. The *amniotic sac,* is the space between the amnion and the fetus. It contains the liquor amnii and the fetus. It dilates the os uteri; and protects the fetus, placenta and umbilical cord from pressure.

5. *Premature rupture of the membranes* may complicate labor and render it difficult. *Treatment* consists in dilating

the cervix, either by the rubber bag or manually, and then delivering by forceps or any other means that may appear preferable.

6. The most common occurrence that may suddenly change a favorable condition of labor into a dangerous one, is probably *uterine inertia*. The *treatment* consists in: removing the cause if possible; the exhibition of chloral, quinine, opium, or bromides; massage of the uterus through the abdominal walls; Walcher's position; rupture of the membranes may be advisable. Oxytocics should not be given.

HYGIENE.

2. Hygienic precautions to be taken in treating a case of tuberculosis: "The patient's quarters should be free from dust and admit of spending many hours daily in the open air in all weathers, properly sheltered, and, if very ill, lying wrapped in a hammock or reclining chair. His bedroom should be well aired at night, draughts being avoided. The room should be uncarpeted and free from hangings. It should be often cleaned and periodically disinfected. All sputum should be collected in paper spit-cups, which should be burned daily. Smoking should be forbidden. Harm is done by any exercise which results in fatigue, and while fever exists it should not be attempted at all. Patients should be taught the necessity of practicing lung gymnastics and breathing only through the nose, which should be kept clear and free from occlusion by secretions, or an hypertrophied catarrhal mucosa. * * * The clothing should be woolen, but not too heavy, or sweating is increased; and a flannel nightgown and loosely knit leggings should be worn at night in cool weather. The skin should be cleansed by daily sponge-baths of lukewarm alcohol and water."—(Thompson's *Practical Medicine.*)

NEUROLOGY.

1. *Nerves* are protoplasmic structures capable of conveying impulses from one part of the body to another.

The *chief divisions of the nervous system*, are: (1) The cerebrospinal system, consisting of the brain, spinal cord, and the nerves attached thereto. (2) The sympathetic nervous system.

2.

CRANIAL NERVES.	EXIT FROM THE SKULL, THROUGH:
1. Olfactory.	Foramina in the cribriform plate of ethmoid bone.
2. Optic.	Optic foramen.
3. Motor oculi.	Sphenoidal fissure.
4. Trochlear or Patheticus.	Sphenoidal fissure.
5. Trifacial.	
(1) Ophthalmic.	Sphenoidal fissure.
(2) Superior maxillary.	Foramen rotundum.
(3) Inferior maxillary.	Foramen ovale.
6. Abducens.	Sphenoidal fissure.
7. Facial.	Stylomastoid foramen.
8. Auditory.	Internal auditory meatus.
9. Glossopharyngeal.	Jugular foramen.
10. Pneumogastric.	Jugular foramen.
11. Spinal accessory.	Jugular foramen.
12. Hypoglossal.	Anterior condyloid foramen.

4. The *function of the white matter*, is to transmit nerve impulses; of the *gray matter*, to receive or send out nerve impulses.

5. *Reflex actions* are involuntary or unconscious movements due to suitable stimuli. They depend upon the integrity of the *reflex arc*, which is a complex made up of: (1) A surface capable of receiving an impression; (2) an afferent nerve; (3) a nerve cell capable of receiving and also of sending out impulses; (4) an efferent nerve, and (5) a surface capable of responding in some way to the impulse conveyed by the efferent nerve.

Reflexes are classified as: (1) Superficial, (2) deep, and (3) visceral.

Example: The patellar reflex consists of a contraction of the extensor muscles of the leg and a movement of the foot forward when the ligamentum patellæ is struck; the quadriceps extensor must first be slightly stretched by putting one knee over the other. Its integrity depends upon a healthy condition of the entire reflex arc, consisting of tendon, afferent or sensory nerve, posterior roots, and anterior horn of the spinal cord, the efferent or motor nerve, and the muscle itself.

6. *The pathology of infantile paralysis:* "The disease is an acute exudative inflammation with destruction of tissue, but without suppuration. It affects chiefly the anterior cornua of the spinal cord, especially of the lumbar and cervical enlargements. It is not, as a rule, diffuse, but often the brunt of the trouble is felt only by certain cell groups. These are destroyed, and after a time connective tissue takes their place. In rare cases the larger part of the central gray and some of the white matter are involved. Later a certain amount of sclerosis occurs in the lateral columns. The anterior roots and motor nerves atrophy. The muscle tissue also wastes, and its place is supplied by connective tissue." (Dana's *Nervous Diseases.*)

MEDICAL JURISPRUDENCE.

1. In both melancholia and mania there is a general perversion of the mental faculties, but the former is usually accompanied with more or less depression, and the latter with more or less excitement.

2. *Paranoia* is a primary chronic form of insanity, occurring especially in degenerates, and marked by hallucinations and delusions which are systematized, *i. e.*, exhibit a logical connection and sequence, so that the patient from his perverted ideas, in which he firmly believes, draws logical and coherent influences. (From Duane's *Medical Dictionary.*)

PHYSIOLOGY, OPHTHALMOLOGY, AND LARYNGOLOGY.

1. *The changes which are produced in the blood by aeration* take place in the capillaries of the lungs, and are: (1) The giving up of the CO_2 by the venous blood, (2) the absorption of oxygen during inspiration, (3) the blood is cooled, (4) it also loses a small amount of watery vapor, and (5) the color becomes red.

2. There are two normal heart sounds which follow in quick succession, and are succeeded by a pause. The first, or systolic, sound is dull and somewhat prolonged; the second, or diastolic, sound is sharper and shorter. The sounds may be expressed by the syllables *lubb—dup.*

The first sound is heard best at the apex beat in the fifth left intercostal space; the second sound is heard best over the second right costal cartilage.

The *causes* producing the *first* sound of the heart are not definitely ascertained; the following are supposed to be causatory factors: (1) the vibration and closure of the auriculo-ventricular valves, (2) the muscular sound produced by the contraction of the ventricles, and (3) the cardiac impulse against the chest wall.

The *second* sound is caused by the vibration due to the closure of the semilunar valves.

3. The *functions of the spinal cord* are: (1) The conduction of impulses and impressions; (2) as a series of nerve centers.

The *special centers in the spinal cord* are the centers for (1) cilio spinal center, (2) for sphincter of bladder, (3) for sphincter of rectum, (4) for erection, (5) for contraction of uterus, (6) for maintaining tonus of muscles.

4. *In the capillaries:* It is here that all the changes occur which take place between the blood and the tissues of the body. Oxygen and the products of digestion and absorption are conveyed to the tissues, and carbon dioxide and waste matters are taken up and carried away from the tissues.

5. Bread consists of proteid, carbohydrate, and a trace of fat.

The *proteid* is converted into proteoses and peptones in the stomach, and in the small intestine (by the action of pepsin and trypsin, respectively).

The *carbohydrate* is converted (slightly) into dextrin and sugar in the mouth, by the action of the ptyalin of the saliva; also in the small intestine (by the action of amylopsin) into maltose.

The *fat* is emulsified and saponified in the small intestine, by the action of steapsin. Bile also has some slight effect on starches and fat.

6. (*b*) The *functions of the skin* are: Protection, excretion, secretion, regulation of the body temperature, absorption, sensation, special sense of touch, respiration.

7. The *functions of the liver* are: (1) The secretion of bile, (2) the formation of glycogen, (3) the formation of urea and uric acid, (4) the manufacture of heat, and (5) the conversion of poisonous and harmful into inert material.

The function of the kidneys, is: (1) To secrete (or excrete) urine; (2) the production of an internal secretion.

8. *Myopia* is a condition in which the antero-posterior diameter of the eye is abnormally long, and parallel rays are focused in front of the retina.

Presbyopia is a condition, due to advancing age, in which there is gradual loss of the power of accommodation, and consequently the near-point recedes beyond the distance at which the patient is accustomed to read.

Hypermetropia is a condition in which the antero-posterior diameter of the eye is abnormally short, and parallel rays are focused behind the retina.

Astigmatism is a condition in which owing to a greater curvature of the eye in one meridian than in others, the refractive power of the eye varies.

9.

	GLAUCOMA.	IRITIS.
Age	Over forty.	Any.
Tension	Plus.	Normal.
Congestion	General, especially scleral.	General, especially circumcorneal.
Cornea	Cloudy, and steamy surface.	Cloudy.
Anterior chamber.	Shallow.	Unchanged.
Pupil	Dilated, oval.	Contracted, synechiæ.
Pain	Severe, continuous.	Especially at night.
Vision	Much reduced.	Somewhat reduced.
Treatment	Eserine, pilocarpine, iridectomy.	Atropine.

(From Alling and Griffin's *Diseases of the Eye and Ear.*)

In *Keratitis*, there are: Pain, photophobia, lacrymation, poor vision, the cornea is infiltrated and "steamy." When due to congenital syphilis, the symptoms of the latter are also present.

10. *Mechanism of Accommodation.*—According to Helmholtz, the lens is an elastic structure, and when released from the flattening influence of its suspensory ligament tends to assume a spherical shape. During accommodation the ciliary muscle contracts, drawing forward the choroid and relaxing the suspensory ligament; this diminishes the tension of the lens capsule and allows the inherent elasticity of the lens to increase its convexity.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.	
Alabama	W. H. Sanders, Montgomery	Montgomery	July 13
Arizona*	Ancil Martin, Phoenix	Phoenix	April 5
Arkansas*	P. T. Murphy, Brinkley	Little Rock	April 13
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco	April 6
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	April 6
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	March 9
Delaware	J. H. Wilson, Dover	Dover	June 15
Dist. of Col'bia	Geo C. Ober, Washington	Washington	April 13
Florida*	J. D. Fernandez, Jacksonville	Tallahassee	May 19
Georgia	E. R. Anthony, Griffin	Atlanta	May —
Idaho	W. F. Howard, Pocatello	Boise	April 6
Illinois	J. A. Egan, Springfield	Chicago	April 15
Indiana	W. T. Galt, Crawfordsville	Indianapolis	May 25
Iowa	Louis A. Thomas, Des Moines	Des Moines	
Kansas	R. A. Light, Chanute	Kansas City	
Kentucky*	J. N. McCormick, Bowling Green	Louisville	April 27
Louisiana	F. A. LaRue 211 Camp Street, New Orleans	New Orleans	May 20
Maine	Wm. J. Mayburry, Saco	Portland	March 9
Marvland	J. McP. Scott, Hagerstown	Baltimore	June 15
Massachusetts*	E. B. Harvey, State House, Boston	Boston	March 9
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Ann Arbor	June 8

THE ZOOPHIL-PSYCHOSIS.

A MODERN MALADY; WITH ILLUSTRATIVE CASES.

By CHARLES L. DANA, M.D., LL.D.,
NEW YORK.

UNDER the general head of constitutional psychopathic states, there is a group of psychoses which have various names and groupings. The list includes what is usually called neurasthenia, hysteria, psychasthenia, phrenasthenia, obsessive psychosis, compulsive psychosis, neurasthenic psychosis.

There stand out among all these conditions, which have the general names of psychoneuroses, three groups which are easily recognized and differentiated: They are neurasthenia, hysteria, and psychasthenia, or obsessive psychosis.

In neurasthenia there is a local or general, but genuine weakness of the psychic and nervous functions.

In hysteria there is a pathological activity of the subconscious mind so that morbid bodily and mental phenomena result.

In psychasthenia, there is a morbid activity of the conscious mind which produces disordered mental and bodily states, but there is no serious loss of control in the relation of the victim to his environment, so that it is not an insanity in its usual sense.

This psychasthenia or obsessive psychosis has been most actively studied in recent years, for it seems to be the disease of our civilization—a kind of occupation psychosis of modern life. It is not hysteria, though hysteria and it are often united. It is not neurasthenia, though this is almost always associated with it at its beginning, at least.

Though there is an unstable constitutional state behind it, yet this may not be very important and most often the disorder is the result of environmental or autogenetic causes. It is produced by bad methods of education and training, acting on minds very sensitive to suggestion and impressions from without and within; minds lacking in power to handle the problems of life, and to see things in their right proportion. Modern activities are too strenuous for this kind of mental organism which is meant for a life of simplicity, moderation, and restraint. The present popular "absorbent" method of education, which lets the mind follow its interests and take the line of least resistance, is a potent factor in the pathogenesis. For through it the power of inhibition becomes weakened or lost; and the mental life is approximated to the conditions of dreaming.

The zoophil psychosis is a modern type of mental disorder belonging among the psychasthenic or obsessive insanities—though really not an "insanity" in the general sense. It is characterized by the tormenting ideas and worrying fears of this psychosis, but it has underlying it a morbid affective state, or as Raymond and Janet call it an "*invraisemblable amour*," toward certain persons and animals. This anomaly of the emotions is not usually referred to as part of ordinary types of this class of disorders; but it is a most important feature; and it may even exist as the dominant thing in the psychosis.

Some phases of this disorder have been incidentally referred to by Raymond and Janet, who have called it a "zoophilie" but it has not been, so far as I can find, specifically presented. They report the case of a woman who became *bouleversée* for three years because her cat had died of cancer of the head. They also give the history of a woman who became obsessed with remorse because she had given away her cat, and the animal had later died. She had the usual train of symptoms going with the obsession: defect of attention, brooding, inability to work, insomnia, etc. "She had another symptom almost as bad as the despair, viz., an impossible love of animals pushed to the degree of disease, a *zoophilie*." She was always surrounded by four cats, which she loved and looked after more than her children. She lost a child but did not much mind it. She lost a cat and was melancholy for eight months. Meantime she became pregnant; had a miscarriage; the joy of this event cured her melancholia. They add that Zoophylie is a frequent symptom among degenerate and psychasthenic patients. Obsessions et Psychasthenie, Vol. II, p. 447.

Magnan, in 1884, wrote an article entitled "De la Folie des Antivivisectionistes" (Soc. de Biol. 27), but this is a different thing.

Ballet in his chapter on "Intermittent Morbid States of the Emotions" describes a "Zoophobia" and its opposite a "Zoophilie," one of the forms of the "voluptuousness of compassion." That which demonstrates the morbid character of this state, he says, aside from the abulia and emotionalism, "is the indifference often complete of the Zoophiles for their own relatives and friends and for human suffering generally—to which indifference there is sometimes added a veritable cruelty. A patient of Morel, who would faint at the sight of a sick animal, "did not fail to rent his windows on the days of executions and force his domestics to go and see them." (Traité de Pathologie Mentale, p. 726.)

In order to show correctly what I mean, and to prove at once that the condition is most real, I will cite the following cases:

CASE I.—*Zoophilic Anxiety Obsession.* A man aged 35, married, no children, came to me suffering from general neurasthenic symptoms. His early history was that he had been always in fairly good health though of a nervous temperament and subject to migraine. His habits were good and he had had no infection. He had lived much of his time in the country, keeping a stable, hunting, breeding dogs, and having many pets. In the last two or three years he had had a great deal of business and family trouble. This wore on his health, and when he came to me he had what is usually called neurasthenia. He could not sleep well; nor do any work

without great fatigue and an ensuing headache. He could not read or use his eyes for any long time. He was easily tired and had lost his interest in his work and pleasures.

He had always been very careful of the comfort of animals and disliked to see them badly treated in the slightest degree; this was especially so of horses. He did not care so much about the dogs. His concern for horses, originally a natural and humane one, grew on him as his health failed; so that he finally gave up keeping them or using them, because their possible discomforts worried him so much. A little trouble with his horse would keep him awake nights. He came to the city, but now the horses of other people bothered him. It gave him real suffering to see a horse checked up, or whipped, or docked, or driven fast. At last he could not travel about in the city with any comfort; the sight of a horse with his head up would give him so much distress; and the chance stroke of a whip by a cab driver was like a blow on his own body. Being a man of leisure, he traveled a good deal, but he finally had to avoid regions where there were horses, altogether, for he would be sure to see something to distress him and then he could not sleep. He had been fond of Italy but he did not dare to go there now on account of his sensations about horses, and the cruel way in which as he remembered they were treated by the Italians. Certain parts of the South he would not visit for the same reason.

His neurasthenic state was not due to this mental condition, but was rather the result primarily of family and personal troubles. But having got into an asthenic state his obsession grew steadily worse. It interfered with his comfort in life. He could only live in certain places and only travel under certain conditions. Away from the sight of a horse he was not distressed by his anxiety for the general welfare of the horse. In fact, he had not even joined an antivivisection society, though he did carry the badge of the S. P. C. A.

He would discuss his feelings with great candor, and recognized that it was an unnatural and unreasonable state of mind. But he could not shake it off. It was his only morbid psychosis, and in every other line he was an intelligent and cheerful sort of person.

In the course of two or three years he got stronger and better, and finally to a large extent mastered his morbid worry; so that he could even go to Italy.

Case II.—*Zoophil-Obsession.* A lady about 40 years old, married but childless and not desirous of children, lived with her husband and sister in a quiet suburb of a large city. Her interest in life lay, to some extent, in her sister and husband and house, but it was mostly in sick cats. She could not bear to have a cat suffer. She made her home a hospital for stray sick cats; and the house was always full of them. If she heard a "meowing" at night she was unhappy and would wake her husband and make him go out and catch the animal, if he could and bring it home. The man's life was made utterly wretched by this condition of affairs, and I was consulted.

The patient herself was a woman in good general health, fairly intelligent, but unsocial, unsexual, and interested only in her domestic and animal affairs, and the conduct of her husband, for she was of a very jealous and exacting disposition, ruling the situation by her selfish querulence. The cat obsession was only one phase, though the most disturbing one, of an unstable constitution; it dominated the situation. Her views on animal suffering were in the abstract, on a high ethical plane, while her conduct was on the lowest possible. She did not, like my other patient, have any "insight" or appreciation of her lack of consideration for the human side of her household, or of the real folly of her point of view. The mental state was more of a quasi-delusional type, yet it led to the same anxious worry and apprehension characteristic of the obsession. She naturally belonged to some kind of zoophilic society, and even organized a little society of her own.

This condition had gradually developed during a period of about five years; until she had become the chronic victim of the cat obsession. She was advised treatment by a gynecologist, for there was some absence or perversion of instinct in her case.

This patient had a sister living with her who had been insane twice, but was now well. She was, if possible, a little more affected by the cat-love than my patient. It would be difficult to imagine a more morbid household.

These cases are examples of fine feelings gone wrong; in the one case involuntarily as the result of an overgrown sentimentality; in the other as the result of a habit selfishly and foolishly nursed into an unmoral mode of life.

The attitude of the civilized communities to animals has undergone great change in the last century. We breed them with greater care for our own practical use or pleasure. We train them better; we kill them less ruthlessly, and exterminate them with some intelligence; in general, there is an enormous advance in the concern for their welfare. Along with this beneficent and creditable advance, there have developed radical changes in our view of animal intelligence. We assume that this intelligence is not of a special animal brand, but is somewhat like our own, though working more automatically. Its greatest asset is the instincts and instinctive feelings; it has acute perceptions in a narrow range; it has the power to remember concrete things and to associate the memories with some result; hence a kind of reasoning exists; but it lacks the power to form concepts or abstract ideas. It has the simpler emotions, *i. e.* those associated with agreeable surroundings, satisfaction of needs or punishment. It has the instinctive passions brought out in defense of life and for the propagation of species. It has not the higher feelings that go with ethical and esthetic concepts. There is a dim and dreamy consciousness, but it is doubtful if the dog, for example, feels a special sense of personality, or (as a man does) consciously separates himself from the world about him. As the automatic and instinctive activities are the main thing, consciousness and with it sensibility are necessarily less acute. Thus we now recognize in animals an intelligence which has a close kinship with our own.*

*About three hundred years ago an oration was delivered at the University of Padua in "Praise of the Dead" whose bodies had been dissected by the anatomist, Professor Julius Casser. Their was then very acute sensitiveness on the subject of dissection of human bodies. Incidentally, the orator shows how far beneath the human body was the animal. "The bodies of animals," said the speaker, "are the neglected domiciles of the brute mind. The body of man is the habitation of the Divine Spirit made beautiful by God himself. They have the composition of Brutes; man reveals the admirable and orderly construction of a being who is the end of all things, the Epilogue of Nature." "Collaudatio Mortuorum," Pisa, 1618.

But when new things are added to our civilization we do not always assimilate them properly, for there is a large class of the unstable, and of the uneducated or over-educated who eagerly seize on what most appeals to their sensibilities, which are developed in excess of the judgment.

In one of Joseph Conrad's stories he describes the character of a gentle but very feeble-minded youth, who while rather unmindful of human trouble, was exquisitively sensitive to the suffering of animals. When the cabman casually whipped his tired horse, "Stevie" gets down promptly from the box, quivering with distress, and insists on walking. He is not worrying at all about his paralyzed mother who is inside the carriage; but the lash on the horse's hide makes him sick with distress. It is not uncommon in mentally defective children to see them show an abnormal sensibility towards animals. It may take the form of passionate interest in and devotion to them; or perhaps of cruelty and absence of any pity at the sight of suffering. Both the excess and the defect are found in this same kind of mentally defective. And Mr. Conrad's character is correctly drawn, and from perhaps some living model.

However, it is really more often in another class that we find this morbid mental state, which can be called *zoophil psychosis*. Speaking very generally, there are three forms of mental defect which are of congenital origin; idiocy, imbecility and "constitutional psychopathy." This last is a vague and not a very good term, and includes among other things that class in which there is not necessarily a lack of intelligence, but, there is lack of stability; the subjects have a mental constitution in which there is a constant tendency to a morbid misdirection of thought, feeling and will. They are persons, often of correct ideals, but they are the victims of fixed and often tormenting ideas (obsessions) of morbid fears, and scruples, of worrying anxiety over trifling details; and of excesses in the affective life. All this is worse when they become run down and neurasthenic.

So far as the zoophil psychosis is concerned, it shows itself both in (1) fixed and tormenting ideas and (2) an emotional hypertrophy which carries a naturally noble sentiment to the point of disease. With both states there are morbid fears and worries.

(1) The fixed idea takes usually the form of a kind of quasidelusion that the animal world is constantly suffering from or in danger of the brutality of man. To an extent this is true, but not to such extent as to lead an individual to acts of oppression and feeling of alarm.

(2) The hypertrophy of affection leads to a continual state of alarm, jealousy, and concern for the object beloved, whether it be a baby, a dog, or the cause of religion. The psychosis is really the expression of a selfish and weak nature.

A very kind-hearted person, for example, may be also very indolent and very selfish—the combination is not uncommon. Now, it is much easier to pet a dog or nurse a kitten, than to tell the exact truth, or speaking more concretely, to nurse the sick; provide thoughtfully for the poor; or keep watch over the temper and make a household comfortable. Thus the kindly feelings of the indolent and unintelligent often take this line of least resistance; and then the feelings and interests grow, until the care for the pets vastly exceeds that in any other unselfish work. The dog is plump and over-cared for; and the cat is more happy than the husband. As Janet says: It is easier to love a cat than a man. Its nature is more simple; its demands more limited; its responses are definite.

In not very stable minds, it becomes especially frequent nowadays that the emotional interests overshadow the judgment and the power of control; so that worry and concern are the complements of love and devotion. Black care sits not behind the "horseman" nowadays, but hangs upon the mother and housekeeper; the father and the bread earner; and the amateur philanthropist. When there is deep affection there should be concern, but in these patients there is more; there are the ever present worry and irritability, and restless anxiety to do something.

It happens that many people cannot nowadays go out into a city's streets and not be distressed continually at the sight of tired, overworked and badly driven horses; or over some very thin looking and ungroomed dogs. They are so eager to observe the unhappy horse that they do not see the human suffering. I confess that after 20 years of experience with cab-driving in this city, I have grown sympathetic to the driver more than to the horse, for on the whole the driver is good to his horse and has a harder lot.

It having been my lot to look after the human sick, I feel that their needs are immensely greater than those of the dog, because their capacity for suffering is so immensely greater, and the suffering of one human being involves a group of others; thus the sick or invalid mother cripples a whole household and her death sends a whole group into mourning.

The animal being dumb is helpless, but so is the baby; and so practically are the sick poor, while the defective child is vastly more the slave of circumstance than the dog or cat, which have chances everywhere.

This all seems very common-place, but it has its application. I plead for sick humanity, and against the excesses in such sentiment for animals, as leads to selfishness and injustice and the development of more psychopathic states. There is growing up an enormous mass of artificially cultivated tenderness towards a supposititous suffering. There will come next tears over the suffering of a fading flower, and sorrow over the unquenched thirst of the withering plant.

This lack of proportion in the kindly sentiment is harmless enough generally, but it develops by mutual encouragement among the unstable and by self-indulgence, until the individual becomes the victim of a psychosis and a source of distress to self and friends, or demoralization to family and of serious social injustice.

DANGERS ASSOCIATED WITH REMOVAL OF THE TONSILS AND ADENOID GROWTHS.

By F. C. ARD, M.D.,

PLAINFIELD, N. J.

Recognition of the evil results due to the presence of adenoids and diseased tonsils is now general. The campaign of education carried on for the past fifteen years or more has resulted in a widespread knowledge of the symptoms indicating their presence, popular articles in the magazines have spread this knowledge among the laity, and it is now not an unusual occurrence for mothers to bring their children for operation, having made the diagnosis themselves.

As a result, the operation is now done generally and often with but a vague idea of the risks involved and the accidents which may occur. A study of the literature will soon satisfy one that the procedure is not trivial, and there is much to substantiate the claim of some writers that the modern operation for the removal of tonsils and adenoids should be considered a major, rather than a minor one.

The ease with which chloroform is administered, together with the belief among medical men that children bear chloroform well, makes it naturally the anesthetic of choice. Careful investigation, however, proves that many deaths have resulted from its administration, and it is now becoming generally recognized that children having what is known as the status lymphaticus are not good subjects for chloroform anesthesia. Few of the deaths following its administration are reported. I have personal knowledge of two unreported cases, where death resulted before the surgeon had an opportunity to begin the operation. Two or three narrow escapes in my own practice led me many years ago to give up the use of chloroform in these cases, and I cheerfully endure the inconveniences of ether, knowing it is associated with far less danger to my patient. Alarming or fatal hemorrhage following the operation is sufficiently frequent to require preparation on the part of the operator for this complication. In a rather extensive search of literature I find eighty-five cases reported. Death resulted in fourteen of these cases and recovery in seventy-one. I have a report of three cases ending in recovery in my own practice to add to the list. It is undeniable that only a small percentage of cases are reported. Dr. Chevalier Jackson stated in 1906, at a meeting of the British Medical Association, that he had tied the carotid artery in postoperative tonsillar hemorrhage six times, yet no report of any of his cases was found in my search.

The causes of hemorrhage may be divided into constitutional and local. The constitutional causes include hemophilia, all forms of anemia, exophthalmic goiter, valvular disease of the heart, and operation during menstrual period. The local causes are abnormal distribution of blood-vessels, incomplete operation or operating in the presence of an acute inflammation. In the fourteen deaths, a history of hemophilia was secured in seven. This large percentage in the fatal cases does not obtain in those where recovery resulted.

Damianos and Hermann give hemophilia as a cause of severe postoperative hemorrhage in only 4 per cent. of the cases reported. This is obviously incorrect, although due allowance must be made for a natural tendency on the part of an operator to consider a "free bleeder" as a hemophiliac. Among the number of cases of alarming hemorrhage, several were operated on about the time the menstrual period was due. Knowing the constitutional causes, we can eliminate these cases by securing a careful history.

Among the local causes abnormal distribution of blood-vessels is considered by Barrell and Orr as a more frequent cause of hemorrhage than is hemophilia, and they mention particularly large pulsating vessels, situated on either side of the pharynx behind the posterior palatine arch. Dupuy states that he has several times observed a vessel the size of a crow quill, superficially situated and pulsating, coursing along the junction of the posterior and lateral walls of the pharynx. I have observed this anomaly once. The much dreaded injury to the carotid has occurred but once, and then due to an anomaly in its course. The source of arterial bleeding is almost invariably the tonsillar artery.

Hacking observed six cases of severe hemorrhage after tonsillotomy, in all of which the cause of the bleeding was injury of the posterior pharyngeal pillar. These tonsils were attached to the floor of the tonsillar niche with a broad base, the lower end reaching deeply below the level of the root of the tongue, and were closely applied to the pharyngeal pillars. The injury was due to the choking movements of the patient crowding the posterior pillar into the instrument.

Hemorrhage calling for interference may be immediate, belated, or secondary, the direct belated hemorrhage being most common, according to Burger. A comparatively large number of cases occurring on the fifth day is noticeable in these reports, indicating that one of Nature's methods is exhausted before another method becomes effective. Secondary hemorrhage may occur even later, as Brown reports a case fifteen days after operation.

For control of hemorrhage following the removal of adenoids, persistent spraying with solution of adrenalin or hydrogen peroxide may result in some of the solution reaching the bleeding surface. These remedies may be applied by means of cotton on applicators passed through the nose or mouth, but the most effective method is by packing the upper pharynx. This is the measure most frequently resorted to and with satisfactory results.

The faucial tonsil is more readily accessible, and here other methods may be employed. Pressure with the fingers has repeatedly controlled hemorrhage; the applications of various remedies, such as solution of iron, tannic and gallic acid, adrenalin, hydrogen dioxide, and the electrocautery, have been successfully used.

To combat the persistent forms more radical measures are indicated, and a very effective procedure is suture of the palatine arch. Escat describes the method as follows: A strong ordinary curved needle is employed for the purpose, held in a needle-holder and armed with a strong silk thread, 40 cm. long. The two pillars are pierced from the anterior to the posterior in case of the left tonsil, and from the posterior to the anterior in case of the right tonsil. In the vicinity of the supratonsillar fossa, the two pillars may be transfixed together. One suture is not sufficient as a rule to close the space, and another may be placed one or two centimeters below the first. As the ends of the silk thread are outside of the mouth it is very easy to conduct the loop as far as the pillar with the fingers. In certain cases, however, the suture has only the effect of transforming the tonsillar groove into a canal, the hemorrhage continuing behind the suture, as in a case observed by the author. Under these conditions, it becomes necessary to slip a tampon, made of absorbent cotton, into the canal. This tampon should be made the size of the little finger and may be imbibed with a hemostatic, such as hydrogen peroxide, antipyrine solution, ferropyrin, or adrenalin. It is inserted into the supratonsillar fossa from above downward, with the aid of curved forceps, and is pressed into the space until it emerges below the inferior suture; traction is then made on the lower end, in order to wedge the tampon in firmly; the tampon can be removed at the end of twenty-four hours; the sutures are to be removed only provided the withdrawal of the tampon does not give rise to hemorrhage.

Nicoladoni's suggestion to render the bleeding tonsil accessible from the outside in desperate cases of tonsillar hemorrhage, to remove the organ and to close up the pharynx by suturing the pharyngeal pillars to each other, is described in the *Wiener klinische Wochenschrift*, No. 9, 1902. The operation is recommended because ligature of the common carotid is much too dangerous and moreover not absolutely reliable, in view of the anastomoses from the other side, and because it is not always positively known that the tonsillar artery is the bleeding vessel in every instance. I find no instance where this method of controlling hemorrhage has been applied, but the ligature of carotid, either common or external, has been done frequently. Three of these cases occurring in my own practice are as follows:

Case I.—A. D., male, age 8. Adenoids removed with forceps and curette, ring knife used in removing submerged tonsil; more or less oozing from the surface of the tonsil on one side after operation. I left directions to spray the throat with hydrogen peroxide if the bleeding continued. On the same evening I was called to see the patient and was informed that bleeding had been continuous since the operation; on inspection, blood could be seen trickling down the side of the throat and the patient's general appearance indicated loss of considerable blood. With a long shaft needle used that day in a case of cleft palate, I sutured the palatine arch and packed the cavity so formed with gauze soaked in adrenalin solution. Twenty-four hours later the gauze was removed, and forty-eight hours from the time of operation, the sutures were removed with no recurrence of bleeding.

Case II.—M., female, age 15. She had been subject to frequent attacks of inflammation of the tonsils. Submerged tonsils removed with ring knife. Bleeding shortly after operation assumed alarming proportions and the palatine arch was sutured in same manner as in Case 1, which promptly controlled the bleeding; the packing was removed in twenty-four hours, the sutures in forty-eight hours. Three or four days later, I was summoned to the house on account of hemorrhage recurring, but it ceased spontaneously before my arrival and required no treatment.

Case III.—Adenoids removed with forceps and curette in the early afternoon. That night the family physician was called on account of hemorrhage. Monselle's solution of iron used in the nose arrested hemorrhage. I saw the patient, who lived in an adjoining town, the following morning, and she showed the effect of the loss of blood, being very anemic and prostrated. There was no further recurrence.

In these three cases there was no history of hemophilia and the patients were all apparently in good health. In the first two cases, the method employed was similar to that described by Escat, although I had not then seen his article. The gauze strip, I believe, will be found quite as satisfactory as cotton.

One author, Wingrave, has observed thirty cases of rash, after removing tonsils and adenoids. The rash appears as a rule on the second or third day and may be papular, roseolar, or erythematous in character, sometimes involving the face and extremities; it may persist for two or three or even five days when it rapidly subsides. Desquamation follows in certain cases. General symptoms are insignificant.

Acute articular rheumatism and endocarditis have been reported as following operation. Hemnebert reports five cases of diphtheria subsequent to operation.

Various septic diseases have occurred. Coley reports three cases under his own observation, where septic infection of the serous membranes resulted. Severe inflammation of the cervical glands, giving rise to severe and persistent symptoms, was observed by Gronbeck in four cases. Putnam has seen two cases of meningitis follow operation. Injury of the posterior pillar, uvula, vomer, vertebra prominens, and even the Eustachian tube, may occur when the operator is unskillful, and two cases of fracture of the end of curettes are reported, in one case the broken end was removed with much difficulty, and in the other case the fragment passed through the bowels.

Middle-ear inflammation, occasionally complicated with mastoiditis, has frequently developed after tonsil and adenoid operations.

I have added to my paper a condensed report of a large number of cases of fatal and non-fatal complications. These cases represent but a small percentage of those that have actually occurred, but there are a sufficient number to warrant the statement that due care is not taken in securing a history; too little time is given to preparation for operation and often times insufficient knowledge and experience are possessed by the operator.

Stucky, F. A.: Sudden deaths following the removal of tonsils (*Memphis Lancet*, June, 1899). Death occurred nine hours after the removal of tonsils and adenoids, as the result of hemorrhage. The fatal outcome is referred by the author to sepsis and hemorrhagic diathesis.

Stucky, F. A.: Removal of tonsils and adenoids, followed by fatal results (*American Practitioner and News*, March 1, 1899; *Annals of Otology, Rhinology, and Laryngology*, May, 1899). The operation, which was urgently required, was unattended by complications, until profuse hemorrhage set in two hours later, but this could be readily controlled. However, the patient (a young child) died at the end of seven and a half hours after the hemorrhage, presumably as the result of shock.

Schuchardt: Sudden deaths after excision of enlarged tonsils, due to hemorrhage, asphyxiation, or shock (*Aerztliche Sachverständigen Zeitung*, No. 7 1900). The patient was a girl thirteen years of age, of lymphatic chlorotic constitution, who died suddenly during the removal of the right tonsil (the left had just been ablated without trouble), presumably as the result of heart failure, a not uncommon occurrence in individuals of this type.

Thompson, W. B.: A case of sudden death after an operation for adenoids (Medical Record, Aug. 18, 1900). The patient, a child of twelve years, was operated upon under chloroform anesthesia for adenoids and enlarged tonsils. Death occurred a few minutes later, preceded by cyanosis, weak pulse, enlarged pupils, and shallow respiration. The customary stimulants, traction of the tongue, and finally tracheotomy, were employed, but without success, and the cardiac action and respiration did not return, although artificial breathing was kept up during an hour and a half. The death is referred to heart failure.

Thurly, E. L.: Remarks on the after effects of operation for removal of adenoid tissue at the vault of the pharynx (*Journal of the American Medical Association*, May 1, 1901). The author says that a

few cases of general sepsis have been noted after interventions of this kind. A case of subsequent fatal meningitis occurred in his personal experience. Adenoid operations have been known to be followed by inflammation of the middle ear and the accessory sinuses, sometimes subsiding at the end of a few days, but sometimes followed by purulent catarrh. It is advisable to avoid similar operations during epidemics of influenza, diphtheria, or other infectious diseases.

Stewart, F.: Death after the removal of tonsils and adenoids in a hemophilic child (*Lancet*, November 15, 1902). The patient, a boy seven years of age, was operated upon under ether anesthesia. Severe hemorrhage followed, but was promptly arrested. In the course of the next four hours, both sides of the neck and the left cheek became swollen by bloody extravasates. These swellings extended as far as the sternum and clavicle. Dyspnea appeared, and intubation was performed, followed by tracheotomy. The patient died at the end of thirty-two hours. The pharynx, larynx, and cervical tissues were found to be infiltrated with blood. There was nothing to be elicited in the personal or family history concerning hemophilia. No further hemorrhage from the sites of the operation had occurred after the interference.

Goldsmith, Perry G.: A fatal case of secondary hemorrhage four days after the removal of adenoids (MEDICAL RECORD, September 27, 1902). The patient was a child who was operated on for obstructive deafness due to enlarged faucial tonsils. The operation was not unusual, and the condition of the patient on the second and third day after the operation was apparently satisfactory; on the fourth day, however, repeated and alarming attacks of hemorrhage set in, resulting fatally in a few hours; there was no history of hemophilia. The patient was under the care of the family physician at the time of death, and as no postmortem could be obtained, the cause of the hemorrhage remained unknown.

Damianos and Hermann: Fatal secondary hemorrhages, following tonsillotomy (*Wiener klinische Wochenschrift*, No. 9, 1902). The patient was a man twenty-three years of age, in whom a fatal hemorrhage occurred about an hour and a half after the ablation of a hypertrophied tonsil with the Fahnestock tonsillotome. The bleeding immediately after the operation was inconsiderable. There was a certain tendency to hemophilia. The incision passed in the plane of the external capsule of the tonsil, where the trunks of the tonsillar arteries are as yet undivided, and one of the trunks was shown at the autopsy to have been injured in its lateral wall. The author cautions against overradical ablation of the tonsils.

Burger, H.: Fatal hemorrhage after adenotomy (*Tijdschrift voor Geneeskunde*, No. 2, 1903). The patient was a boy eleven years of age, who succumbed to hemorrhage twelve hours after amputation of the three tonsils in spite of tamponing of the nasopharyngeal space. At the autopsy it appeared that the patient had suffered from fully developed leukemia.

Putnam: Adenoid operations and mortality (*New York Medical News*, March 12, 1904). The author observed a case in which an operation upon adenoid vegetations was followed by purulent meningitis, with a fatal outcome. He believes that similar fatal sequelæ after adenoid operations are of more common occurrence than is usually assumed. Some time ago he had occasion to observe the outset of meningitis after this operation in another patient, a young man twenty years of age. It is probable that in these cases infectious material was absorbed by way of opened lymphatic channels.

Wales, A. E.: Cavernous Sinus Thrombosis after Adenotomy. (*Archives of Otology*, February, 1908.) The following case was observed by the author at the Massachusetts Charitable Eye and Ear Infirmary, Boston. A boy aged seven entered the Infirmary February 2, 1906, for the removal of adenoids. Operation under ether. Too great force with a Beekman curette, in the hands of an inexperienced interne, combined with a thin cortex of the inferior surface of the basilar process of the occipital bone, may account for the following history: Immediately on recovering from the effects of ether, the boy complained of occipital headache, which increased in severity. On the third day he developed tenderness over the right mastoid process with pain; drum membrane slightly reddened; all landmarks visible; redness and bulging of the posterior wall of the external auditory canal. The boy had a septic appearance. A mastoid operation was performed; the antrum was apparently normal. Pus was found in the deep intracranial cells around the sinus and tip. No culture was made. The right infraorbital region began to swell and become erythematous, resembling erysipelas, and the patient was removed to contagious ward. Septic temperature; no improvement after operation; tenderness in back of neck after operation; condition worse; temperature very irregular, ranging as high as 107° F.; tenth day right eye developed exophthalmos, chemosis of lids, and optic neuritis. Diagnosis thrombosis of cavernous sinus. He became comatose and had frequent epileptiform attacks. The left lid and eye began to show the same signs as had appeared on the right eye. Death occurred on the fourteenth day. Necropsy; thrombosis of both cavernous sinuses. Right sinus filled with pus; left clot not broken down; pus in mastoid cells; no clot in sigmoid sinus or jugular bulb. Streptococcic infection. Conclusion: The basilar process of the occipital bone may be injured in removing the nasopharyngeal tonsil. Too much force should be avoided, just enough force to cut the adenoid growth, which depends upon the consistency and sharpness of the cutting instrument. Injury to the basilar process may, by extension, cause infection of the sphenoid sinus, and finally thrombosis of the cavernous sinus.

The following cases of fatal hemorrhage following adenotomy are reported by Dupuy in his article in the *Laryngoscope* for January, 1906.

Preble: (*Boston Medical and Surgical Journal*, Vol. 138, 1898). The patient, a girl of eleven; hemorrhage occurred on the seventh day, postnasal packing, no history of hemophilia.

Schmieglow: (*Centralblatt für Chirurgie*, 1897). Male; death immediately from injury of the carotid, by curette, due to an anomaly in its course.

Sochs: (*Journal of Laryngology*, 1900). Boy aged ten; hemorrhage occurred two hours after operation and continued for two days. Solution of iron and packing applied; positive history of hemophilia.

Bliss: (*Trans. American Laryngological Association*, 1900). Boy aged seven; hemorrhage occurred twelve hours after operation; history of hemophilia on maternal side; postnasal packing, ergot and saline transfusion.

Kenefick: (*Laryngoscope*, 1898). Boy aged four years; postnasal packing.

Delavan: (*New York Medical Journal*, 1892). Hemophilia.

Newcomb: (*American Journal of the Medical Sciences*, Vol. II). Boy aged three; bleeding occurred four hours after operation; no physician called.

Barkan: (*Occidental Medical Times*, 1894). Boy aged six; no history of hemophilia.

Hooper: (*Laryngoscope*, 1890). Pharynx scraped with finger; incomplete operation; hemophilic history.

A sufficient number of non-fatal cases only are reported to call attention to the various complications and the method employed for their control by different operators. Many reported cases are not included.

Huber, F.: Lateral pharyngeal abscess following tonsillotomy. (*Medical Review*, September 30, 1899; *Pediatrics*, September 15, 1899). The abscess developed in connection with excision of the tonsils in a child who had previously suffered from a severe postcervical abscess. In the opinion of the author, the old inflammatory focus was started up again by the traumatism of the operative interference.

Klein: (Danish Oto-Laryngological Society, meeting January 20, 1900). A case of secondary hemorrhage on the fifth day after the removal of adenoid vegetations. The patient, a girl of fourteen years, was operated upon with Gottstein's instrument on January 5, 1900. On the 7th she developed angina, and on the 10th, at 4 P. M., there occurred a profuse hemorrhage (half a liter) coming from the nasopharyngeal space and lasting five hours. Alarming hemorrhage.

Quinlan, F. J.: (*Laryngoscope*, April, 1900). Alarming hemorrhage following the removal of the tonsils. The hemorrhage occurred between two and three hours after the performance of tonsillotomy, and was severe enough to require an infusion of physiological salt solution. The patient, an adult, recovered.

Hope, G. B.: An instance of primary hemorrhage following amygdalotomy (*New York Medical Journal*, March 3, 1900). The patient, a woman of twenty-six years, came out of the anesthesia (chloroform) immediately after tonsillotomy had been performed with Mackenzie's instrument. Bleeding was extremely severe from the first instant, and with slight remissions lasted for over three hours. Large coagula formed in the throat, requiring the forceps for their removal and the patient was almost stifled by the blood flowing down the larynx. The ordinary hemostatics such as local applications of cold, cocaine, solution of antipyrin, hydrogen peroxide, all proved entirely useless and the hemorrhage could be controlled only by energetic application of the thermocautery, after the patient was already highly anemic. During the brief instants in which inspection was possible, the hemorrhage could be seen to originate from an arterial branch on the right side, in the anterior portion of the cut surface. The tonsil had been so radically ablated that the stump was entirely hidden by the pharyngeal pillars, except during contraction of the fauces.

Riviere: Comments on 150 operations for adenoid vegetations. (*Lyon Médical*, July 11, 1900). With special reference to complications, the author observed epistaxis and inflammation of the cervical lymphatic glands. He employed the curette for the removal of adenoid growths. Hypertrophied tonsils removed with the bistury, the tonsillotome or the galvanic knife.

Hagedorn: Severe spontaneous epistaxis after ablation of adenoids (*Bresgen's Sammlung*, II, 1901). The patient was a girl seventeen years of age, who had alarming hemorrhage, from right nostril alone, a few hours after the removal of the adenoids. Rhinoscopical examination showed that the blood came from all parts of the visible mucous membranes in the anterior sections of the nasal cavity. The hemorrhage was controlled by tamponing, but the left side began to bleed, the same findings being demonstrated, and the same treatment proved successful. The hemorrhage in this instance was referred to the fact that the operation was performed three days before the date of the menstrual period; the patient always bled very profusely at that time, so that vicarious menstruation could be thought of; however, the menstrual flow soon appeared in undiminished abundance and lasted the usual eight days.

Getchell, A. C.: Dangerous hemorrhage after the removal of enlarged tonsils and adenoids, with the report of a case. (*Journal of the American Medical Association*, October 5, 1901). The case reported by the author had a favorable outcome. The conclusion is reached by the operator that the tonsils or adenoid vegetations should be removed under the greatest precautions only when the patient is a child less than five years of age.

Wyatt, Wingrave: Tonsillotomy Rash. (*Laryngoscope*, July, 1901). The author reports a series of personal observations, but points out the rarity of this complication. Examinations of the blood, which were carried out in the week following upon the operation, showed with few exceptions an increase of the mononuclear leucocytes. The leucocytosis is rarely demonstrable after the tenth day, and certainly is more than accidental.

Dr. B. Van D. Hedges of Plainfield, N. J., has observed two cases of torticollis following operation. The first was in a boy fourteen years of age. Symptoms appeared on the third or fourth day and lasted two months; the attack was quite severe with some elevation of temperature in the early stages. In the second case, in a girl aged ten, symptoms appeared on the third day after operation and lasted one month. Both patients made a perfect recovery. Dr. Hedges attributes this complication to mild sepsis.

Beveckhaert: Rheumatic complications following ablation of adenoids (*La Belgique Médicale*, No. 46, 1901). The author reports two cases in which the ablation of adenoid vegetations or the nasopharyngeal tonsil was followed, four and five days respectively after the operation, by an attack of acute articular rheumatism, which persisted from two to three weeks.

Christian R. Holmes: (*Journal of the American Medical Association*, March 23, 1901); E. Lowe Farlick (*Laryngoscope*, May, 1901). Holmes reports a case in which the sharp blade of Gottstein curette was broken off at the beginning of the operation for adenoids and could be removed under the greatest difficulties only. Farlick observed a case in which the blade broke off and was swallowed by the patient. Three days later it reappeared per rectum without having caused any damage.

Edgar A. Forsythe: Amygdalotomy Rash (*New York Medical Journal*, December, 1901). The author observed a case of amygdalotomy rash after

removal of a pharyngeal tonsil, in a boy eleven years of age in May, 1900.

The rash appears as a rule on the second or third day following operation, and it may be papulous, roseolar, or erythematous in character. It spreads along the neck, chest, and abdomen, sometimes involving the face and extremities; it may persist for two or three, or even five days, when it rapidly subsides. Desquamation follows in certain cases. The general symptoms are very insignificant. This eruption has the same characteristics as the rash described as surgical or traumatic scarlatina.

W. Wingrave: Tonsillotomy Rash (*Lancet*, August 31, 1902). The author observed thirty cases of rash after removal of the tonsils or adenoid vegetations, in the last seven years, including twenty female and ten male patients.

Lunin: Hemorrhage after the removal of pharyngeal tonsil (*Boln. Gazette*, No. 3, 1902). The author reports five personal observations upon hemorrhage, which occurred at variable intervals after the operation (four and six days later) respectively (in two cases) leading to more or less anemia.

Chappell, W. F.: Operative accidents in the treatment of adenoid vegetations, New York Academy of Medicine, Section of Laryngology (*Laryngoscope*, December, 1902). The speaker observed a case of complete rupture of the palatine velum as the result of adenotomy. Ten days after the operation the child presented an irregular laceration of the velum extending at the free margin upwards to the left as far as the roof of the palate. In swallowing, fluids escaped through the nose.

Abrams said that during his attendance in one of the large Berlin clinics, an assistant had to operate upon a child thirteen years of age. No anesthetics were employed. The operation was performed with one of Gottstein's curettes. Immediately after the introduction of the instrument, the child made an effort to escape and the result was a rupture of the velum, from its free margin as far as its insertion in the hard palate.

Larecky saw in two instances that the uvula was grasped by the operator in the forceps. In one of these cases, it was completely detached.

Phillips witnessed the detachment of a considerable portion of the vomer. The curette usually injures the uvula. He saw a case of laceration of the posterior pillar which required the application of three suture stitches, three days later.

Escat: Treatment of surgical hemorrhage of the tonsils (*Presse Médicale*, August 30, 1902). The author discourses on the treatment of surgical hemorrhage of the tonsils on the basis of a personal observation in a case of severe tonsillar hemorrhage, which he reported in May, 1902, before the French Laryngological Society. The bleeding in this instance was controlled by means of suture of the palatine arches.

Dunbar, Roy: Two unusual cases of hemorrhage following adenotomy and tonsillotomy (*Laryngoscope*, February, 1902). In one of the cases, suprarenal extract was employed prior to the operation for adenoid vegetations, which was followed by hemorrhage, interpreted by the author as vicarious menstruation. The second case was one of hemorrhage three days after the performance of tonsillotomy.

Escat: Tonsillar hemorrhage following the employment of a sharp-bladed morcellator. (*Ann. des Mal. de l'Oreille et du Larynx*, 28, 1902). The patient was a man twenty-seven years of age, in whose case a very severe postoperative hemorrhage lasting four hours was caused by a tonsillotome with a sharp edge. This hemorrhage could only be controlled by the introduction of a tampon into the tonsillar space, after this had been transformed into a canal by means of two sutures connecting the posterior with the anterior pillar, according to Baunn's method.

Three lessons may be derived from this observation: (1) The danger of instruments with sharp edges; (2) the unreliability of the majority of hemostatics; (3) the efficiency of tamponing the tonsillar space after this has been transformed into a canal by suture of the pillars.

Hermann: Hemostasis after tonsillotomy (Fraenkel's *Archiv für Laryngologie*, Vol. XII, 1902). The author reports a case of protracted hemorrhage after tonsillotomy, in a patient forty-six years of age, which was immediately controlled by the application of two sutures, firmly uniting the two palatine arches. This suture is recommended as a prophylactic procedure after every tonsillotomy, when the patient has passed a certain age, or lives at a distance from professional aid, or when the tonsils are of delicate structure.

Homer M. Thomas: Secondary hemorrhage following tonsillotomy (*Illinois Medical Journal*, February, 1902). The author reports a case in which secondary hemorrhage occurred three days after the operation.

Leipziger: Hemorrhage after tonsillotomy (MEDICAL RECORD, 1902). Report of a case in which subcutaneous injections of morphine proved serviceable.

Lee Weber: Secondary hemorrhage on the fifth day after tonsillotomy (*Laryngoscope*, April 12, 1902). The most noteworthy features of the case consisted in the fact that the secondary hemorrhage did not occur until the fifth day after the operation and that the patient was only five years of age.

Mygind, H.: A case of sudden collapse with cessation of respiration and cyanosis (spasm of glottis) as the result of adenotomy; tracheotomy recovery (*Monatsschrift für Ohrenheilkunde*, No. 5, 1902). The patient was a child two years of age, who was operated upon for the adenoid vegetations with Beekmann's instrument, after having suffered from rickets, diarrhea, and bronchial symptoms. The child collapsed at the instant of the operation, respiration ceasing entirely, and the lips turning blue. Digital exploration of the larynx showed it to be free. As the cyanosis increased, inferior tracheotomy was promptly performed and respiration returned at once after the trachea was opened. The operation in this instance was performed without an anesthetic, because the frequent deaths of children nuder these circumstances are referred by the author to the fact that respiratory disturbances occur very readily in this operation. However, he was twice enabled to observe that serious disturbances may appear in cases where no chloroform anesthesia has been employed. Both these cases concerned little children under two years of age, with well-marked rhachitic symptoms. In each instance the operation was immediately followed by laryngoapasm, in connection with stridulous inspiration and cyanosis of the lips. The conditions in these cases lasted no longer than a quarter to a half a minute, after which the passage through the glottis again became quite free. But the situation in both cases was so alarming, while the respiration was arrested that the author

since that time always kept in readiness for instantaneous use the instruments required for the performance of tracheotomy. This measure was found extremely valuable in the management of the case reported above.

Citelli: Acute otitis and mastoiditis after ablation of the pharyngeal tonsil (*Boll. delle Malattie degli Orecchi*, August, 1902). In a case observed by the author, the ablation of the pharyngeal tonsil was followed by the onset of acute middle ear disease and mastoiditis, as the result of improper after-treatment. He concludes that adenoid vegetation should be operated upon and treated solely in the clinics and hospitals, unless there is sufficient guarantee for the patient's rational behavior after the operation.

Hennebert: Clinical remarks on adenoid vegetations (*La Clinique*, Nos. 21-29-30, 1902). The author observed five cases in which operations upon adenoid vegetations were followed by diphtheria.

Montengohl: Complication following removal of adenoids (*Pediatrics*, May 1, 1902). The patient developed chorea and endocarditis subsequent to removal of adenoid vegetations under chloroform anesthesia.

Gronbeck: Some remarks on operation for adenoid vegetations (*Ugeskrift for Läger*, March 21, 1902). In his discussion of the most important postoperative complications, infection and hemorrhage, the author points out the severe inflammations of the cervical glands on both sides as observed by him in four patients and which may give rise to very severe and persistent symptoms. He cautions against the removal of tonsils and adenoids together at the same session.

Weoblews, R.: Complications occurring in tonsillotomy (*Gazeta Lekarska*, Nos. 7-8, 1903). The author discusses in detail a number of postoperative complications, especially hemorrhage, in connection with two cases of peritonsillar abscess, due to tonsillotomy, which were recently reported by Lokolowski.

Bulso, Albert: Alarming hemorrhage following excision of tonsils and adenoids (*Laryngoscope*, March, 1903). The patient was almost exsanguinated eight hours after the operation. An adrenalin solution (1:3000) was sprayed into the nose and throat, physiological salt solution was administered per rectum and finally strong stimulants were employed, with a favorable outcome. The author is of the opinion that the hemorrhages which follow upon tonsillar and adenoid operations may be controlled by the rational employment of adrenalin.

Beady, A. J.: Retrospect of personal experience of the removal of postnasal growths (*Medical Journal of Australasia*, September 20, 1903). The author's experience includes fourteen years with 3,204 cases of operation for adenoid vegetations under employment of various anesthetics. Among these cases there were no deaths. In one instance there was a serious complication on the part of a middle ear; no secondary hemorrhages. Two cases of secondary hemorrhage were observed after operation under local anesthesia; the bleeding was readily controlled in both instances. The hemorrhage was referred to incomplete removal of the growth.

Urban, A. H.: Hemorrhage following tonsillotomy (*American Medicine*, July 4, 1903). The patient was a child, seven years of age, who was admitted to the hospital twenty-seven hours after the performance of a bilateral tonsillotomy. A parenchymatous hemorrhage was visible in the left tonsillar region. The bleeding was controlled with the Paquelin cautery, under chloroform anesthesia. The hemorrhage was distinctly secondary in character, for it began twelve and eighteen hours after the operation. The case was not one of hemophilia and the patient had not previously suffered from acute angina. In all probability, the hemorrhage was referrable to a blood-vessel having an abnormal course.

Ryan, Lawrence R.: Tonsillar hemorrage (*Illinois Medical Journal*, September, 1903). Bilateral tonsillotomy was performed under adrenalin and cocaine, upon a patient twenty-five years of age, and was followed by a severe hemorrhage, but this could be controlled by the local application of tannin and acetanilid. Half an hour later, there occurred a severe secondary hemorrhage, which the author succeeded in arresting by means of the cautery. The bleeding in this instance was referable to hemophilia.

Coley: Endocarditis after adenoid operations (*New York Medical News*, March 12, 1904). One such case came under the author's observation, and he knows of two others in which septic infection of the serous membranes developed after a successful operation for adenoids. This possibility should be kept in mind and the parents should be instructed in regard to precautionary measures for the prevention of septic infection.

Castex: Paris Society for Laryngology, etc.; meeting February 12, 1904. The case was one of paralysis of the palatine velum, folowing operation for adenoid vegetations in a child. Castex assumed the cause to be infection due to imperfect asepsis of the instruments.

Schranum: Sepsis after operation for adenoids (*New York Medical News*, July 23, 1904). The sepsis in this case developed a few days after the operation. The patient was a girl six years of age, suffering from a constant nasal discharge. The anesthetic used was chloroform and every precaution to secure a sepsis to instruments and surroundings was taken. The growth was easily removed, and the bleeding was not excessive, in fact, rather less than usual. When seen four days later, she complained of chilliness and headache; had no appetite and preferred to lie in bed. The whole trouble was considered intestinal, yielding to divided doses of calomel. In the evening, however, she was much worse, with a temperature of 104° F., pulse 140, and respiration 38. She complained of pain in the left ear. On the next day she had a mild conjunctivitis with moderate purulent secretion. Throughout the disease there was nothing abnormal to be seen in the throat; the abdomen continued distended and the bowels sluggish. On the seventh day after the inspection, the symptoms subjective and physical began to subside. The temperature, pulse and respiration were normal on the ninth day. It is remarkable that the medical literature of the past few years contains no similar case.

Cline, L. C.: Grave hemorrhage following tonsillotomy (*Laryngoscope*, December, 1904). Hemorrhage which came near being fatal, occurred in a boy five years of age after tonsillotomy; the case turned out to be one of hemophilia.

Kan, R. L.: A series of hemorrhage after adenotomy and tonsillotomy. Three cases of hemorrhage after tonsillotomy and three after adenotomy, all with favorable outcome. Among the latter, one occurred immediately after the operation, the others at the end of two and six days, respectively.

Wilkinson, Oscar: A case of hemorrhage after tonsillotomy relived by adrenalin (*Journal of Eye, Ear, and Throat Diseases,* July, 1904). The patient was a girl of seventeen years of age, upon whom bilateral tonsillotomy was performed under nitrous oxide. Hemorrhage followed and was controlled by the employment of adrenalin solution and ice. Another profuse hemorrhage occurred at the end of an hour and a half, after the patient had reached her home. Adrenalin was again employed, first externally, then internally (ten drops every fifteen minutes) with successful outcome.

Brown, E. J.: Cases of primary and secondary hemorrhage following removal both with tonsillotome and snare (*Larnyngoscope,* February, 1905). *Case 1.*—Tonsillotomy performed on a man twenty-eight years of age, hemorrhage occurred immediately after the operation and was controlled by long continued compression. *Case 2.*—Removal of tonsils with the snare in a woman thirty-three years of age, fifteen days later, severe secondary hemorrhage ceasing at the end of a few hours. *Case 3.*—Removal of tonsils with the snare, in girl six years of age, followed by hemorrhage two days later.

Henking: The cause and treatment of alarming hemorrhages after ablation of the tonsils (*Archives of Laryngology and Rhinology,* Vol. XVII, 1905). The author observed six cases of severe hemorrhage after tonsillotomy, in all of which the cause of bleeding was referable to a source not hitherto described in detail. As a rule hemophilia, or injury of artery trunks, or vascular anomalies are held responsible, whereas the literature contains but few proofs in support of these arguments. The six cases referred to above all concerned tonsils which were attached to the floor of the deep tonsillar niche with a broad base, the lower end reaching deeply below the level of the root of the tongue and which were closely applied to the pharyngeal pillars; here the source of the hemorrhage was invariably found to consist in an injury of the posterior pharyngeal pillar.

Jackson, Chevalier: At the meeting of the British Medical Association held in Toronto, August 24, 1905, in the Section of Laryngology and Otology, during the discussion of a paper on the employment of the cold snare for the removal of hypertrophic tonsils, Chevalier Jackson states that he had tied the carotid artery six times, on account of postoperative tonsillar hemorrhage. The snare had been employed in one of these cases.

George B. Leland said that he had observed only one case of alarming hemorrhage in the course of the last twenty years. The bleeding subsided after the wound surface had been thoroughly scraped with the finger nail.

Herbert Tilley had noted three severe tonsillar hemorrhages in the course of twelve years.

St. Clair Thompson commented upon the much rarer occurrence of hemorrhage in England than obliged to be the case in America. He was never obliged to tie the external carotid and had observed no more than two cases of severe hemorrhage in thirteen years.

Nettebrock: Hemorrhage after tonsillotomy (Dissertation, Kiel, 1906). The author recommends the following procedure as practised by Helferich, with a favorable outcome, in two cases of postoperative hemorrhage. A long round darning needle, armed with linen thread, is inserted behind the maxillary angle by digital pressure in the buccal cavity. The internal end has attached to it a thick tampon of iodoform gauze, which is firmly pressed against the tonsil by traction from without, tying the threads over a rubber tube.

Cunningham: Hemorrhage after the removal of tonsils (*Southern Medical and Surgical Journal,* January, 1906). Repeated hemorrhage after tonsillotomy in a boy sixteen years of age, controlled by application of clamps.

Chapman, V. A.: Alarming secondary hemorrhage following the removal of the pharyngeal tonsil (*Journal of the Michigan State Medical Society,* December, 1906). The case concerned a boy of sixteen years of age and terminated in recovery.

Barrell, James, and Orr, W. J.: The presence of abnormal blood-vessels in the nasopharynx and the occurrence of hemorrhage after the removal of postnasal adenoids (*International Medical Journal,* December 30, 1906). The authors report three cases of severe postoperative hemorrhage from their practice, which comprised about one thousand operations. Among the cases recorded in the literature, they were enabled to collect seven deaths. The abnormal vessels are large pulsating arteries on either side of the pharynx behind the posterior palatine arch. Upon the basis of their personal observations and the cases recorded in the literature, the authors arrive at the conclusion that abnormal blood vessels constitute a more frequent cause of hemorrhage than does hemophilia.

Avale: A case of secondary hemorrhage after ablation of the tonsils (*Revista Barcelonesa de Laryngologia,* No. 7, 1907). The hemorrhage was controlled by pressing a tampon which had been dipped in hydrogen peroxide, against the tonsillar fossa.

Henkes, J. C.: Hemorrhage after tonsillotomy, and a new method of hemostasis (*Nederlandsch Tijdschr. v. Geneesk.,* 1, No. 4, 1907). The author discusses the cause of postoperative tonsillar hemorrhage, and the methods which have been suggested for their control. His method is based upon the procedure recommended by Hermann and Escat, independently of each other, and consisting in suture of the two palatine arches to each other. Instead of suturing the arches, Henkes employs strong metal clamps or buckles (distance of points, 2 cm.) which are hooked into the two arches by means of forceps constructed for this purpose. After a tampon has been introduced into the tonsillar niche, the clamps are closed. Another forcep serves for the subsequent removal of clamps which can be accomplished without difficulty. The value of this form of interference is illustrated by a case treated according to this method, which the author recommends for adoption.

CONCLUSION.

In Ballenger's new work on Ear, Nose, and Throat, he states that, "In young children, tonsillotomy is not necessarily a hospital operation, as it is rarely followed by either severe hemorrhage or sepsis. In adults it should be a hospital operation on account of the possible hemorrhage and sepsis. A prominent surgeon has said that the tonsil is of greater clinical importance than the appendix; that it causes more suffering and more deaths. If this is true, and I believe it is, the tonsil is worthy of the most serious and painstaking study. The technique of its removal should receive the same careful attention that has been devoted to the removal of the vermiform appendix. In view of the importance of the tonsil from a clinical standpoint, and

in view of the possible complications and sequelæ following its removal, tonsillotomy should be regarded as a hospital operation. If performed in a hospital, the danger from primary and secondary hemorrhage is largely eliminated and infection and sepsis may be diminished in severity and in the frequency of their occurrences."

Subsequent to the reading of this paper, I operated on a boy five years of age. I saw the patient for the first time on the operating table, but my assistant had made careful inquiry as to the presence of hemophilia with negative results. Radical tonsil operation was done with the removal of adenoids. At the time of operation there was free bleeding from the tonsillar region on the left side, which ceased spontaneously. Five days later I was called to see him and found that he had had a profuse hemorrhage, and bleeding was continuous, notwithstanding the efforts of the family physician. Under anesthesia the vault of the pharynx was packed and the child placed on considerable doses of lactate of calcium. The result was satisfactory; the packing was removed twenty-four hours later. The mother was again questioned and she finally remembered that her father had almost "bled to death" on several occasions. The action of lactate of calcium in this case was most satisfactory. Simpson's favorable experience in a case of hemophilia induced me to use it.

604 Park Avenue.

THYMUS ENLARGEMENT ASSOCIATED WITH NERVOUS SYMPTOMS.

A PRELIMINARY COMMUNICATION.

By OTTO LERCH, A.M., M.D., Ph.D.,

NEW ORLEANS,

PROFESSOR OF MEDICAL DIAGNOSIS, NEW ORLEANS POLYCLINIC

The thymus is considered a temporary organ which after the second year gradually diminishes until at the end of puberty little is left. In adults a mass of fibrous tissue and fat, containing small nodes of lymphoid tissue in which Hassal's corpuscles persist, represents the gland up to extreme old age. The arteries supplying the thymus are derived from the mammary and inferior thyroid; the veins terminate in the left innominate and the thyroid veins. The lymphatics are large and arise in the substance of the gland and are believed to terminate in the jugular veins. The nerves are derived from the vagus and sympathetic. Nothing positive is known of the function of the gland.

Thymedectomy proves fatal to rabbits in a few weeks, due to intoxication. Removal of one-half will cause hypertrophy of the other. Removal of the thymus in dogs causes increased output of lime salts and deficient ossification. The thymic veins may become distended in chronic passive hyperemia due to cardiac lesions, and the enlargement has been mistaken for persistent thymus. The enlargement disappears. The most severe congestion may disappear at death and leave no trace at autopsy. Stridor and death have been caused by an acute increase in size of the organ due to an acute hyperemia, the enlarged gland pressing upon the trachea, vessels, and nerves. The aperature of the chest contains trachea, esophagus, great vessels and thymus. The distance from the sternum to the vertebral column is very small and the walls unyielding. A most severe congestion may disappear at death and leave no trace at autopsy. That this is a fact has been shown in frozen sections. Thymus hyperplasia is frequently associated with goiter. After the ligation of the thyroid branches of the thyroid arteries the blood goes to the thymus from this artery.

Abnormal atrophy of the gland has been found associated with progressive and fatal marasmus. The enlargement of the organ is due to congestion, edema, and hyperplasia. The possibility of percussing the thymus has been denied by many, though Hochsinger showed enlargement of the gland by percussion in 26 out of 58 children, verifying his results by radiograph.

After giving in the above short outline about all that seems to be known of this interesting organ, I wish to state that the gland can be distinctly and sharply outlined by percussion in adults up to extreme old age. In all individuals I have so far examined, male and female, I have not found any difficulty. The size of the organ when filled with blood and lymph varies from 2 to 3 centimeters to 12 and 14 centimeters at the base, corresponding to the level of the sternoclavicular joints and clavicles. The apex parallel to the base may join the heart dullness. The area of dullness is represented by a trapezoid, the lateral sides of which are slightly curved, and which is sometimes not larger than a half dollar. As a rule one side, the right or left, of the sternum is larger than the other, more frequently the right, and the dullness is rarely uniform over the whole, and varies from light dullness to flatness in circumscribed spots. To percuss the gland it is best to place patient in an upright position with the head thrown back; light percussion and deep percussion may be used; either method will outline the organ distinctly though not always exactly corresponding. Palpating percussion may be used for control. The results obtained by percussion may be verified by the radiograph and fluoroscopic examination. In a large number of patients a more or less pronounced bulging may be noticed corresponding to the percussion figure, in others again percussion dullness gives smaller borders. This is probably due to the filling of a gland with blood and lymph. The area of dulness is frequently red where the gland is enlarged, and shows distended superficial veins. Position alters the intensity of the dullness and the size of the area. Recumbency decreases and the upright position increases it. That this is due to the outflowing and inflowing blood and lymph can be easily shown by putting the patient on the abdomen on a table so that the chest protrudes over the edge and percussing from below decrease of dullness can be observed, and at the same time the increase and decrease of redness and the filling and emptying of the superficial veins may be seen. Besides, it has been found as stated that even the most severe congestion of the gland observed during life cannot be seen at autopsy, the blood having left the organ as frozen sections have further demonstrated.

The symptoms of the enlargement of the thymus are the symptoms of the functional neuroses, hysteria, neurasthenia and visceral neuroses, and probably of the forms of functional insanity, mania, melancholia, and paranoia. This is so much the case that from the enlarged gland we can predict the severity of the symptoms and from the symptoms the size of the gland; the more pronounced the symptoms the larger the gland, the flatter the dullness, and vice versa. Some symptoms may be considered almost pathognomonic, the dilated pupils, and the rapid pulse changing from 100 beats in

the upright position to 80 or less in the recumbent posture, due evidently to stimulation of the sympathetic nerve and the emptying of the gland in the horizontal position. If the symptoms are more pronounced on one side than on the other the gland is found as a rule larger on that side and the dullness more intense. Of pressure symptoms are especially noticed checking sensations, fulness in the head, difficulty in swallowing, asthma and cough coupled with other symptoms of the functional neuroses.

Enteroptosis with nervous symptoms is almost invariably associated with an enlarged thymus. Some enlargement of the thyroid is sometimes seen and occasionally exophthalmos or bulging of one eye, corresponding to the side of greater enlargement and dullness, and the symptoms of exophthalmic goiter resemble the symptoms of thymic enlargement. Tachycardia and tremor are prominent symptoms of both, though the heart beats seldom more than 120 per minute. The pulse is small, the arteries, mostly contracted, may beat visibly, especially the carotids, and sometimes pulsation between the sternoclavicular joints can be seen. The appearance of the skin is sometimes normal, at times brilliant, and occasionally pasty. The heart sounds are loud and the apex heaving. Irritation and irritability of temper, forgetfulness or rather loss of attention, coupled with hysterical stigmata, and the various visceral disturbances, easy fatigue of body and mind associated with normal muscular strength are often found. Underweight is more frequent than the normal or overweight. Hyperidrosis is frequent and sometimes local, especially in the palms of the hands. Increased urination and palpitation and disturbances of the stomach and intestines are almost always present. That the symptoms are due to thymic enlargement seems to be more than probable. The large amount of blood retained in the organ, increased by fright, anger, and exertion, stimulates the fibers of the sympathetic and vagus; this and the disturbances due to pressure upon the large vessels, esophagus, trachea, and nerves seems sufficient to explain the symptoms. Heredity is another factor that finds easy explanation; and so also the measures adopted to treat the neuroses, especially the rest cure, favor the emptying of the organ of the surplus blood and lymph.

The differential diagnosis is not difficult to make. The ever-present nervous symptoms and the area of dullness (trapezoid), cleaning up on change of position, make it an easy task to diagnose the affection. Finally the action of the Roentgen rays and especially of the high-frequency current causes a considerable contraction of the gland. After an application of a high-frequency current for five minutes a large gland will diminish considerably around the margin. This fact will differentiate it from any other cause that might give dullness on percussion over the top and to the side of the sternum, such as a tumor in the mediastinum, enlarged glands, aneurysm, or dilatation of the aorta. The application of this form of electricity given without any danger will prove one of the most valuable means of treatment, for to some extent the effect is permanent. Specific medication on the lines of thyroid treatment and surgical interference in severe cases may be tried and rest and hygienic treatment can be carried out to good purpose.

I believe that this affection is an entity for which I propose the name "Thymokesis" (abnormally large thymus). The following cases are taken from my records to illustrate the affection.

Miss E. 18 years of age. Since two years nausea and occasional vomiting. Discomfort in the epigastrium, fullness and pressure after eating, appetite poor, bowels constipated. Loss of weight. Patient very nervous, dilated pupils; tremor manuum, exaggerated reflexes. Uvular reflex absent. Right kidney palpable. Lower curvature of stomach at navel, splashing over the whole area. Arteries contracted. Pulse 90. Large area of dullness over top and to both sides of the sternum, especially, as usual, to the right.

Mrs. S. 53 years of age. Trifacial neuralgia on the left side for three years. Unable to see well with the left eye, especially after reading and writing. Both eyes normal, glasses do not give relief. Has had several attacks of blindness in the past year, each lasting several hours. Has suffered from fullness after eating and pressure in epigastrium for years. Suffers from choking sensation and the feeling as of a lump in the throat, and feels occasionally as if her heart was stopping. Arteries contracted. Pulse, standing, 100; lying, 70. Dilated pupils, tremor manuum. Suffers from cold hands and feet and excessive perspiration. Area of dullness over thymus large. To the left of sternum area of dullness large and more pronounced than on the right.

Mr. N. 33 years of age. Complains of dry cough and irritation in the throat. Thinks he has consumption. All organs normal. Patient has gray hair. Weighs 128 pounds and is 5 feet 8 inches tall. Contracted arteries; pulse, standing, 110; lying down, 96. Dilated pupils. Area of dulness over thymus 12 x 9 x 6 centimeters.

Mr. M. 28 years of age. Fourteen days ago his child was bitten by a supposed mad dog, and he commenced to worry about his child and himself. Complains of nervousness and nausea, vomiting, and sleeplessness. Bowels constipated. Organs normal. Urine contains traces of albumin. Has lost eight pounds in weight in the last fourteen days. Area of dullness over thymus is 12 x 8 x 6 centimeters. Arteries contracted, pupils dilated, pulse 90. Under treatment rapid improvement and disappearance of albumin.

Mr. C. 45 years of age; 5 feet 5 inches in height; weight 258 pounds. Complains of shortness of breath after exertion, finds it especially difficult to climb stairs. No nervous symptoms, area of dullness not larger than a half dollar. Diagnosis fatty heart.

Mr. J. 5 feet 6 inches in height; weighs 186 pounds. Complains of shortness of breath. Vein of face dilated. No nervous symptoms. Area of dullness over the thymus as small as in the previous case. Pulse 120 standing, 110 lying down. Diagnosis: Debilitas cordis.

Mr. L. 50 years of age. 5 feet 8 inches in height, weighs 175 pounds. He suffers from chilly sensations, nervousness, cold hands and feet, indigestion, and cough. Brother suffers from exophthalmic goiter. Arteries soft and straight. Pulse 100 standing, 90 lying down. Area of dullness over the thymus is 14 x 10 x 6. Rapidly improved under treatment.

Mr. M. 5 feet 11 inches in height; weighs 220 pounds. Gouty. Organs normal. No nervous symptoms. Area of dullness over thymus very small.

These and others have improved under treatment. I had an opportunity to examine eight patients suffering from functional forms of insanity.

In every patient examined I have found dullness over thymus very large and often amounting to flatness. Also the usual symptoms, dilated pupils, tremor manuum, and exaggerated reflexes.

Thanks are due to Dr. A. E. Fessler, who has rendered me valuable assistance in these investigations.

THE PREVENTION OF EPIDEMICS.*

By MARTIN J. SYNNOTT, A.M., M.D.,

MONTCLAIR, N. J.

PRESIDENT BOARD OF MANAGERS, ESSEX COUNTY ISOLATION HOSPITAL.

THE practice of medicine is not, like surgery, an exact science, nevertheless our knowledge of the etiology of infectious diseases is such that fairly well defined principles have been evolved. It is almost uniformly conceded by scientific men that specific microorganisms are the causative factors of these diseases, and with this knowledge at our command, it is not difficult to work out a rational system of prevention. Much has been done along this line with the result that serious epidemics of contagion are becoming more and more uncommon. If energetic measures are carried out, and efficient means provided by the public authorities for the purpose, progress will be accelerated, until the infectious diseases now prevalent, such as scarlet fever and diphtheria, will be as rare as "spotted fever" or the "black plague" which once decimated Europe.

The administration of the laws affecting public health is fairly well performed in the cities, but in the small towns and rural districts the manner in which infectious diseases spread, and the measures that should be taken to prevent them, are but imperfectly understood, and even members of the medical profession at times seem hardly to realize their significance. Inasmuch as the cities depend upon the country for food supplies, and intercommunication is frequent, it follows that preventive measures must begin in the country, and effective precautions must be enforced there to check the spread of infectious diseases, if epidemics are to be prevented in the cities and larger towns. The local boards of health in many of our villages and smaller towns are not properly trained to cope promptly with health emergencies, and their methods of procedure are still extremely primitive. Preventive measures are unknown or entirely neglected, or carried out in a very imperfect and slipshod manner. The methods of isolation, quarantine, and disinfection in many even good sized villages are so crude and imperfect as to be almost useless. Bad as such conditions are for the community where they exist, they assume even more sinister significance because of the danger to which they expose other nearby towns and cities, where modern and up-to-date methods may be in vogue.

The public mind is only beginning to grasp the principle that various diseases may be largely prevented, if not extinguished, if proper measures are enforced, and that the intelligent expenditure of public funds to this end is the surest and wisest economy. The lowering of the death rate in our cities and large towns is due mainly to the precautions now taken to prevent the more infectious diseases from spreading, along of course with the improvement in the sanitary conditions of the tenement districts, the prevention of overcrowding, and attention to pure food and water. As the public health conditions improve the population becomes less liable to infection and better able to withstand attacks of contagious and other diseases. With improved hygiene, pure food and water, and sanitary homes, epidemics will become more mild and consequently less fatal.

In the rural districts, where no intelligent preparation has been made to combat contagion, panic at the advent of an epidemic is the inevitable result. Proper buildings or sites for detention or isolation hospitals cannot be quickly obtained, and unseemly huts, of forbidding appearance, hurriedly erected, badly warmed and ventilated, located in a wilderness, are the result of such lack of preparation. The patient is taken to such a building, sitting upright in an old rickety, ramshackled, jolting cab. The popular dread of the "pest house" under such conditions is no idle fear.*

In the cities, on the other hand, even with active health measures energetically enforced, the seeds of infection are probably never extinct. Thorough disinfection is not always possible. The movements of each individual member of an infected household cannot be controlled, and the possibilities of communication between different persons are devious, intricate, and intimate. The infectious microorganisms are very tenacious of life, they adhere to all manner of things, and thus infection may spread from a small center. Excursionists, tourists, travelers, and summer boarders may carry infection with them, and scatter contagion in the places they visit. Thus one individual case may start an epidemic.

But while the prevalence of infectious diseases in a large city may be a grave danger to the smaller places in communication with it, on the other hand, as already pointed out, the rural districts and villages are a still greater menace to the cities. Epidemics of scarlet fever, typhoid, and diphtheria in cities have been repeatedly traced to infected milk and water and other food supplies. Quarantine is observed in the country either imperfectly or not at all, and the emigration of persons from infected houses may infect towns. Thus they act and react, one on the other. Innumerable centers over a wide country area converge upon and infect the towns and cities, and *vice versa*, infected cases from the towns and cities radiate over the country, creating new centers of contagion from which the disease rapidly spreads to return again to the towns and cities.

To stamp out an epidemic it must be vigorously and promptly attacked in the district where it first appears, and no amount of money should be spared to do this; otherwise the contagion will spread. Quarantine regulations must be vigorously enforced, and the whole repressive force of the municipality must be directed to the spot where the disease is discovered without loss of time. The up-to-date health officer will watch not only his own city or town but also the smaller neighboring places, particularly if they are known to be careless in matters of hygiene and their health officers inefficient, so that if stray sparks escape into his territory, they may be promptly extinguished. We cannot hope to keep free from infection until all municipalities whether large or small adopt the

*Read before the Orange Mountain Medical Society, at Orange, N. J., Friday evening, Nov. 20, 1908.

*Cf. Dr Roger McNeill's work on "Prevention of Epidemics," page 3.

same standards in health ordinances, and enforce the same remedial measures. The campaign against infection is thus largely educational at the present time, and the country districts must be taught that such measures protect not only themselves, but the urban population as well.

Infectious diseases have been aptly compared, by an English author, Dr. Roger McNeill (Op. Cit., p. 10), to a conflagration, which spreads rapidly in the city, while with slower but equally fatal progress in the country; the distinction being that the spark of contagion cannot like fire be immediately extinguished. But it can frequently be lifted up, removed from other combustible material, and isolated until it spends its force and burns itself out.

The successful prevention of epidemics depends upon the perfect organization of local and State health bodies, the efficiency of school medical officers and sanitary inspectors, thoroughness of quarantine and disinfection, the education of the masses, improved sanitary conditions among the poor, vaccination, prompt isolation, and wiping out of centers of contagion. Before the days of vaccination, prior to 1800, twenty out of every one hundred born died from smallpox. It is now no longer a dread and is easily controlled, providing that health officers observe rigorously the rule in regard to vaccination and revaccination and quarantine in those localities from which smallpox is removed. Health measures applied to other contagious diseases will produce equally gratifying results.

With smallpox, typhoid, scarlet fever, diphtheria, typhus, hydrophobia, we have made a good start, and with the aid of our medical health officers, sanitary inspectors, and bacteriologists, we may hope ultimately to extinguish them, one by one.

With *measles* and *whooping cough* nothing has as yet been done and no efficient provision has been made to prevent the spread of either, yet they are both among the most easily communicated of the contagious diseases, and their isolation should be of the best. The absence of all precautions against these diseases accounts for the almost annual epidemics when whole class rooms in the schools are temporarily emptied. With proper isolation these cases could be limited to their own area and not allowed to spread.* The New York Health Board has been the first to grasp this situation and it deserves praise for what it has already accomplished. Statistics show that these two diseases cause a greater number of deaths than any other infectious disease. Measles causes five times, whooping cough six times as many deaths as smallpox. The mischief is that these little-thought-of ailments, through lack of proper treatment, are allowed to impair the general health, cause permanent lung disease, and even blindness and deafness. Preventive medicine, as applied to these two diseases, has been a failure.

Disinfection must be efficient and should be entrusted to men of intelligence who will observe proper technique and who will be conscientious enough to look for and extirpate all sources of infection. Investigation by health officers must be thorough, and drains, sewers, cesspools, outhouses, domestic animals, rats, insects, etc., all considered as possible factors of contamination. Formaldehyde is at present our most satisfactory fumigant, but this is often used by unintelligent persons. The three important points about formaldehyde disinfection are: (1) to use it in sufficient quantity, (2) to make sure the premises to be disinfected are sufficiently tight to retain the gas, and (3) to have the apartments where it is used heated to at least 60° or 70° F. Special vacuum apparatus has been devised for formaldehyde disinfection, in hospitals and institutions, of clothing, bedding, etc., which has the advantage over steam in not damaging the fabric, in not fixing discharge stains in linen, and in being not only as effective but also more expeditious.

Isolation hospitals prevent the multiplication of infected centers and check the immediate spread of such diseases, hence they are a most important factor in the prevention of epidemics. A large proportion of our population live in one, two, or three room dwellings, where it is impossible to isolate the sick from the healthy. Such small apartments or tenements are as a rule badly built, drained, and ventilated. When sickness occurs, if it is infectious, others get it. When early removal to a hospital is possible, and prompt fumigation is carried out, there is rarely further disease in the house. We see this often even in the case of smallpox. Hospital provision and efficient disinfection reduce the danger of spreading infection to the minimum, and change the infected house from a plague spot and menace to the public for weeks or months, to a healthful abode.

A small town can hardly afford its own isolation hospital, while local jealousies and want of cohesion between neighboring towns usually prevent the erection of a joint or combination hospital. In New Jersey provision is made for county hospitals for contagious diseases, to be erected by the Board of Chosen Freeholders of each county, and managed by a board of six managers, appointed by the director of that body. Under this plan, by providing at the outset for the proper care and treatment of the various infectious diseases, real economy is best conserved. Any other policy is apt to degenerate into parsimony and it must be borne in mind that the work which the County Hospital, when completed, will perform, will be work formerly done and paid for by the separate municipalities of the county, and that they will be relieved of this expense when the County Hospital is available. The care of patients suffering from infectious diseases by the separate municipalities presents greater difficulties every day with the rapid increase of population.

It is more economical to provide a well appointed hospital than to incur all the expense, misery, and death of an epidemic. The primary effect of such a hospital is to prevent infection from spreading by the seclusion or separation of persons suffering from contagious ailments from all other persons who might catch these diseases. Every hour's delay gives infection a chance to spread.

One bed should be provided for each 1,000 population. Isolation hospital zones are not unhealthy, and the danger of atmospheric dissemination of contagion from the hospital to neighboring inhabitants has been greatly exaggerated. Forty feet is considered a sufficiently safe area of air space between buildings. Close observation in cities fails to reveal any increase in the number of contagious diseases in hospital zones.

An isolation hospital should be made up of several buildings of one or more units, each unit to have its independent entrance, serving kitchen, sterilizer, and toilet arrangement. A building of

*Dr. Robert J. Wilson, Superintendent of Contagious Hospitals, New York City.

this type may be made to serve a great many purposes. It can be used for either sex, for straight cases, mixed infections, quarantine, or observation, according to the exigencies of the occasion.

Mixed infections are the *bête noir* of isolation hospitals. A patient suffering from diphtheria is more liable to catch scarlet fever than a well person, because his resisting power has been lessened, and in his weakened condition he is more likely to die. Hence in such an event, if this occurs in a hospital, the death rate is increased and the possibility of damage suits is risked.

Many doors of exit are important in an isolation hospital, because if a case of mixed infection is discovered in a ward, it can be removed quickly with the minimum of exposure to the other patients, and with the least chance of contamination to other parts of the building where it occurs.

Let us consider briefly the complications an isolation hospital is sure to have to contend with. Starting with straight diphtheria, we may have diphtheria and scarlet fever, diphtheria and measles, diphtheria and varicella, diphtheria and pertussis, diphtheria and German measles, diphtheria and vaginitis. Without proper isolation these complications would naturally run on to diphtheria, scarlet fever, and measles; diphtheria, scarlet fever, and varicella; diphtheria, scarlet fever, and pertussis; diphtheria, scarlet fever, and German measles; and then diphtheria, measles, and varicella and diphtheria, measles, and pertussis, etc. The same applies to scarlet fever, making almost countless complications. This is no theory, but each one of these combinations has actually occurred in practice. This shows the necessity of providing for the care of cases of complications.

When a case of one of these various mixed infections is discovered in a ward, not only must this case be promptly removed and isolated, but no new patient should be admitted to this ward until the quarantine period for the disease has expired. Thus you will see that isolation must be provided for the cases of mixed infections as well as for new patients coming to the institution during the quarantine. Again patients will be admitted from time to time with diphtheria or scarlet fever, who, prior to admission, have been exposed to some disease other than the one for which they have been admitted, and in which the incubation period has not been passed. Cases of this kind cannot be admitted in the general ward, but must be held under observation until after the period of incubation for the disease to which they were exposed has passed.

Private rooms or rooms reserved for nurses on the general hall of a hospital cannot be used for observation, for if a disease to which a case has been exposed were to develop, and the patient were removed through such a general hall, the entire service would be exposed to that disease, and the whole building would have to be held under quarantine until after the incubation period had passed. A room used for this purpose should have its own entrance and toilet, and be entirely independent of other parts of the building.

Cases of vaginitis may be safely treated in private rooms, as vaginitis is not contagious in the strictest sense of the word, but is only carried by the attendants taking care of such cases. While vaginitis spreads rapidly in a ward from case to case, on account of their close proximity, when the infected cases are placed in separate rooms and are cared for by separate attendants, it does not spread and there is no need for special isolation.*

It is not necessary of course to provide for the possibility of all these contingencies occurring together because rarely more than one or two of the complications enumerated above occur at one time. But it will be economy to provide at the outset several small buildings in addition to the general wards, suitable for isolation of mixed infections and complications, so constructed that they can be divided into two or more rooms with separate toilet and kitchen accommodations. Such a building may be erected without great expense and all the material necessary could be purchased for about $1,000. This has been done in New York successfully and the construction performed by the Health Department's own employees. The building for observation cases should be divided into several small compartments each a unit in itself, with a separate entrance, each room having a capacity for one adult bed and two cribs.

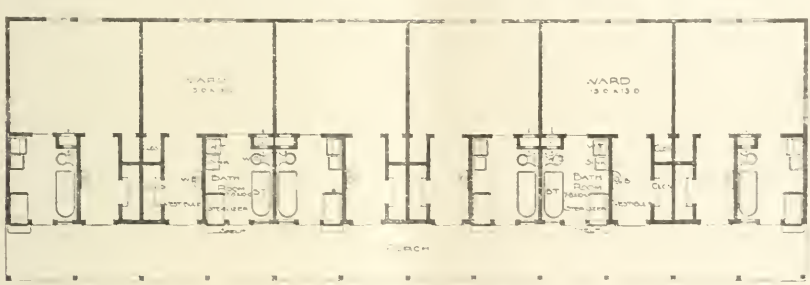

Fig. 1.—Proposed Observation Ward.

It is not necessary for these rooms to have the required amount of air space for the number of patients possible to place in them in an emergency, for the reason that under most conditions there would be only one patient in a room, and that patient there for a very limited time. Each compartment should contain a toilet and children's bath tub, this also to be used as a hand basin, if economy has to be considered.

Plans for an observation building of six compartments, and plans for a building of two wards, suitable for smallpox, quarantine purposes, or cases of mixed infection, are shown herewith. By making the central division absolutely tight in the sec-

*Dr R. J. Wilson

ond plan, this building could be safely used for two diseases, as each ward has a separate entrance, kitchen, and toilet arrangement. Such a building would be well adapted for measles, cases of which will be occurring continually as a complication of other diseases, and unless we provide for its isola-

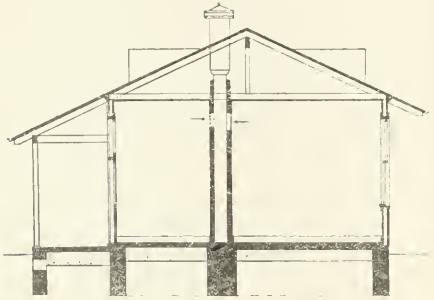

Fig. 2.—Proposed Observation Ward, Transverse Section.

tion, every child admitted with scarlet fever or diphtheria will, in the course of a week or two, develop measles, thus lengthening the time of its stay in the hospital, thereby increasing the cost of maintaining the institution, and adding to the mortality.

The ward space may be increased indefinitely in this plan. A fixed inspection window in the partition between the nurse's room and ward, would be an advantage in enabling the nurse to observe the patients from her room. By enclosing the side porch a dressing room could be improvised for discharging patients.

Smallpox.—It is not necessary to make an elaborate provision for smallpox. At the Kingston Avenue Hospital in Greater New York—one of the largest and finest isolation hospitals in the world—three small rooms, located in the morgue, are all the provision made there for this disease. There will be months of every year when not a single case of this disease will exist in the county.

The writer's judgment and experience in the matter of the construction of isolation hospitals may be summed up as follows: (1) An administrative plant, large enough to provide for growth and development. This should include sleeping rooms for all employees. The nurses and orderlies should not sleep in the infected buildings. It will be found to be economy as well as humane to look after the health of the working staff. (2) At least three general hospital buildings for "straight" or uncomplicated diseases. Each building should contain two wards, entirely independent one from the other, providing for the separation of the sexes, or in an emergency for two diseases. The second plan (Fig. 3) shown herewith is well adapted for this purpose, if the dimensions allowed in it are increased to meet the special conditions of the locality. Each ward in each building should be a complete unit, with independent entrance, serving pantry, and toilet. These buildings need be only one story high, but if built higher, the second floor should be reached by outside stairway, and there should be no intercommunication through elevator or dumb waiter shafts or in any other way. The two floors of a building so constructed could safely be used for different diseases. (3) In addition to the regular hospital buildings, there should be at least two small buildings, one for mixed infections or quarantine, the other for observation purposes. These latter buildings need not be of costly construction, because they will be in use only part of the time, and by a limited number of patients. (See Figs. 1 and 3.) (4) An efficient system of sterilization. A vacuum apparatus for formaldehyde disinfection, large enough to receive an adult mattress, should be installed near the laundry. Small steam or formaldehyde sterilizers should be installed in each unit of each building. These small sterilizers will be useful to disinfect dishes, gowns, dressings, etc.

Tuberculosis.—Only those who have made a special study of isolation and of the necessity for it can be fully impressed with the importance of the

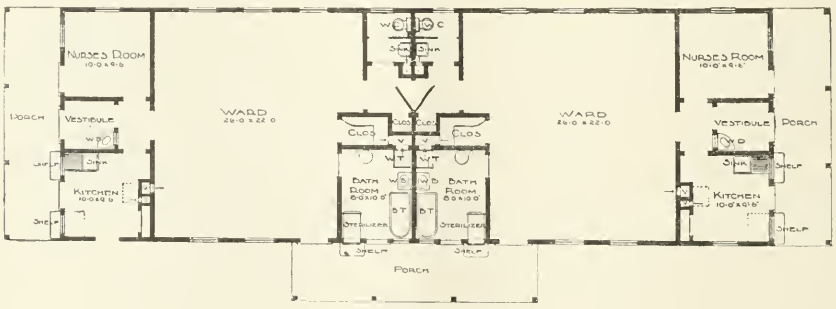

Fig. 3.—Proposed Isolation Ward.

Under normal conditions, a small, but sanitary building, providing for two wards and eight or ten patients, on the plan of Fig. 3, would be ample. When no smallpox exists, this building could be used for other purposes, such as we have enumerated above. It would be a foolish waste of public funds to try to erect a building large enough to provide for an epidemic of smallpox, because during an epidemic hundreds of cases occur. At such times temporary emergency buildings or tents must be provided.

subject. This explains in a way the difficulty in obtaining sufficient appropriations from governing bodies to properly carry on the work. The average public office holder is not qualified by training, education, or experience to understand the requirements of scientific medical hygiene. It has taken years of patient labor on the part of public health officers in the United States to obtain such inadequate and imperfect provision for the isolation of contagious diseases as now exist. Diphtheria and the exanthemata are fairly well provided for, but in the matter

of other of the infectious diseases almost nothing has been done. This is lamentable when we consider the terrible and terrifying ravages made by tuberculosis. In this County of Essex alone, statistics show that more deaths are due to this disease than to any other cause. During the year 1907 there were recorded 899 deaths from consumption, and in the first 6 months of 1908, 536 deaths from the same cause. In the thickly settled communities the percentage of deaths to the population is much greater than in the country districts. This is undoubtedly due to the infectious character of the disease.

Most thoughtful men are convinced that public provision for the segregation and isolation of at least those suffering from tuberculosis who are willing to accept it, is necessary and desirable. The dangerous cases are the ones occurring in the tenement districts, in unsanitary surroundings, among the very poor, and in the crowded quarters where hygienic precautions cannot be observed, and where sunlight, fresh air, and proper food are conspicuous by their absence. Such patients are the ones that often clamor vainly at the doors of our general hospitals for admission, and they would welcome with gratitude the open door of a properly conducted State or county or municipal institution.

The desperate and incurable cases, especially among the aged, are serious dangers to others wherever they exist. And even if their cases are hopeless, hospital segregation at least removes them as foci of infection to the community at large.

If the same number of deaths occurred annually from scarlet fever, diphtheria or smallpox, as occur from tuberculosis, the public would be alarmed, and any sum asked for by the health officers would be readily appropriated by the authorities. This shows what education has done along other lines, and the same may be done for tuberculosis.

It rests largely with the medical profession to bring this about. Concerted action on our part can accomplish much, if only by encouraging discussion among the laity, thus awakening interest, and creating a general demand for public action. Where sentiment, as expressed by the press and individually, is overwhelmingly in favor of action along certain lines the public officials will not turn a deaf ear.

Buildings for tuberculosis need not be expensive. Shacks large enough for eight patients to sleep in, with a warm dressing room and toilet, have been built at White Haven, Penn., and elsewhere for $500 each. Tents are suitable for day camps and in warm weather in places where no mosquitos or flies exist. They are not a success in cold weather, because the patients in them cannot be made to practise personal hygiene. They go to bed with their clothes on, and will not wash or bathe properly. A warm dressing room and toilet are a necessary adjunct, no matter what style of building is adopted.

Many institutions and sanatoria are open for the incipient cases, but the chronic and incurable patient finds all such places closed to him. Here lies the danger to the public health. Provision of adequate facilities for the reception and care of such cases is an imperative necessity. This is the most important single factor in the suppression of the disease. The New Jersey laws give the health authorities power to remove forcibly and detain such consumptives as are for any reason a menace to others and to the public. It would seem that no great difficulty should be met with in inducing county officers to provide funds for the erection of the necessary buildings.

PERITHELIOMA OF THE CAROTID GLAND.

By JOHN DOUGLAS, M.D.,

NEW YORK.

ASSISTANT SURGEON ST. LUKE'S AND BELLEVUE HOSPITALS, INSTRUCTOR IN SURGERY N. Y. UNIVERSITY AND BELLEVUE MEDICAL COLLEGE.

The comparatively small number of cases of perithelioma of the carotid gland, reported in medical literature, would appear to be sufficient justification for the report of the following case:

A. E., female, age 23, domestic, born in the United States, referred to the writer by Dr. J. A. Heitlinger, noticed a small mass about the size of a marble in the left side of the neck several months ago. The tumor was painless and seemed to increase slowly in size, but at times appeared to be larger than at others. There were no subjective symptoms, except that one week before examination the patient complained of hoarseness, which she attributed to a "cold." Unfortunately no laryngoscopic examination was made at this time. The previous and family history was negative.

Physical examination showed an oval tumor 3½ by 2½ by 1½ cm. in the left side of the neck, at the anterior border of the sternomastoid muscle on a level with the superior margin of the thyroid cartilage. The mass was firm in consistency, the surface was smooth, it was freely movable laterally but not in a vertical direction. The skin was freely movable over the tumor. It was not tender and a slight transmitted pulsation was present. No enlarged lymphatic glands were felt. A diagnosis of tuberculous cervical lymphatic gland was made and the patient was referred to Bellevue Hospital for operation.

Operation.—An incision about 6 cm. in length, parallel with the creases of the skin of the neck, was made over the tumor, which was found to be situated in the bifurcation of the common carotid artery. The posterior portion of the tumor lay between the external and internal carotid arteries, which deeply grooved its surface. Its capsule, which was exceedingly vascular, was quite adherent to the sheaths of these vessels. It was possible to remove the tumor without injury to these vessels or apparent injury to any nerves. However, the patient's hoarseness was more marked after the operation, and laryngoscopic examination showed paralysis of the left vocal cord, and marked congestion of the mucous membrane of the larynx, especially about the arytenoid cartilages. A recent laryngoscopic examination, for which I am indebted to Dr. Cornelius Coakley, shows that the left vocal cord is still paralyzed but that the thickening in the larynx has almost disappeared, which would account for the improvement in the patient's voice.* It is difficult to account for this paralysis as the recurrent laryngeal nerve was a considerable distance from the field of operation; the hoarseness was present before operation, and the increased post-operative aphonia may have been due to the congestion and thickening of the laryngeal mucous membrane, resulting from traumatism at the time of operation.

Pathological examination of the tumor made by Dr. Chas. Norris, pathologist of Bellevue Hospital,

*When seen recently the aphonia had entirely disappeared, and the patient's voice was perfectly normal.

proved the growth to be a perithelioma of the carotid gland.

The most recent and complete review of the literature on the subject is that of Keen[1] and Funcke, published in 1906, in which they report one case and review the literature of twenty-six additional cases. For the report of these cases, as well as an admirable account of the etiology symptoms and pathology of perithelioma of the carotid gland, the reader is referred to this paper.

Keen collected twenty-seven operative cases including his own, one case in which no operation was performed and two cases reported from postmortems. In the twenty-seven cases there were seven deaths, a mortality of 27 per cent., due principally to pneumonia from cutting the vagus, or to brain disturbance as a result of ligation of the carotids. In addition to the deaths as an immediate result of operation, one patient died a year after the removal of the tumor from recurrence, and there were three cases in prospect of death from recurrence which had already occurred at the time of Keen's report. One additional case reported but not operated upon was fatal as a result of malignancy. In 18 cases all three carotids were ligated, the external carotid alone in 2 and the jugular vein in 13. The pneumogastric nerve was injured in 6 cases, the sympathetic in 2, the lingual in 2, and the hypoglossal in 4. In addition, Da Costa,[2] in an analysis of fifteen cases, included in Keen's list, calls attention to injury of the facial and recurrent laryngeal nerves in two cases of postoperative paralysis of the vocal cord, and reports that the superior laryngeal nerve was injured in his own case.

Since the publication of the article by Keen and Funcke the writer has found the report of but three cases, which, together with one unreported case operated upon by Dr. Wm. Downes, and his own case, make a total of thirty-two operative cases. A brief résumé of the reports of these cases follows, they being numbered as they have been reported after Keen's twenty-seven cases, so as to bring the literature on the subject up to date.

Case 28.—Cook.[3] Man, 29 years old, colored. Tumor in left side of neck sixteen years. Operated on nine months previously, but tumor had recurred and at time of second operation was 7 x 5 x 5 cm. in diameter. Diagnosis of aneurysm of the carotid made. All three carotids were ligated and excised with the tumor. Patient died one hour after the operation from hemorrhage and shock.

Case 29.—Rivet.[4] Woman, 49 years old, had tumor opposite angle of jaw for seven years, but rapidity of growth had only been recent. At time of operation was size of egg. Diagnosis made of parotid tumor or aberrant goitre. Operation was followed by aphonia and for two or three weeks there was difficulty with deglutition. Recovery.

Case 30.—Zondec.[5] Man, 63 years old. Had tumor in right side of neck for fourteen years. At time of operation tumor measured 7 x 5 cm. All three carotids tied at time of operation. Recovery.

Case 31.—Coley and Downes.[6] Man, 29 years old. Tumor in the neck of several years' duration. Size of hen's egg at time of operation. Diagnosis. Sarcoma of tonsil. External carotid ligated at time of operation, and hypoglossal nerve injured. Recovery after operation, but death one year later from recurrence.

Case 32.—Author's case reported above.

Therefore in a total of thirty-two cases upon which operations were performed, we find eight deaths as a result of operation, an immediate mortality of 25 per cent., and six cases in which recurrence occurred. There were twenty cases in which all three carotids were tied and three in which the external carotid alone was ligated. And in addition to the nerve injuries reported by Keen, as mentioned above, we must add one additional case each of injury to the hypoglossal, superior laryngeal, and facial nerves, together with three cases of postoperative paralysis of the vocal cord.

Be cause of the high mortality and the danger of injury to other important structures, Keen, in concluding his article, agrees with Reclus and Chevassu when he quotes: "Only rapid growth of an apparently malignant nature justifies operation."

A study of the reported cases, however, shows certain facts. The histories extend over a period of several years, in one case the growth being present for thirty-seven years, in others from four to twenty years. It would appear, then, that in the beginning these tumors are benign in their nature. But the history of the appearance of rapid increase in the rate of growth, the report of enlarged glands in six cases, and of recurrence after operation in six cases, while one patient died of malignancy without operation, shows that a considerable number of these cases become malignant that were apparently benign in the beginning. And if one were to follow the conclusions of Reclus and Chevassu and of Keen and wait to operate until malignancy is apparent and the chance of recurrence greater, as well as the difficulty and seriousness of the operation increased, the prospect of cure is certainly not brilliant.

Moreover in but few of the cases reported was a correct diagnosis made before operation, and it would appear that by calling attention to the existence of these tumors, an opportunity might be obtained of operating before they had attained a great size, and the operator knowing with what he had to deal could by free incision and careful dissection, and an accurate knowledge of the anatomy of the region, avoid injury to the nerves which in several cases has been one of the causes of the high mortality and disagreeable after-results of operation. Examination of the illustrations accompanying Keen's article shows that where the tumor has attained considerable size, its removal without ligation of the carotids would be impossible, but when the tumor is small it can often be removed without this additional risk.

In view of these facts, while recognizing that there may be a certain number of cases where a large but slowly growing tumor, without evidence of malignancy, exists in a patient whose age or whose general or arterial condition would make the danger of postoperative shock, or of brain disturbance after ligation of the carotids, especially great, in whom operation would be inadvisable; it would appear to the writer that instead of advising against operation in all cases until rapid growth or malignancy occurs, more good could be accomplished by an effort at early diagnosis and removal of the tumor while the risk is less, and the prospect of lessened mortality and of an ultimate cure without recurrence greater.

A CASE OF RETINITIS DUE PROBABLY TO ACUTE LEAD POISONING.

By G. W. VANDEGRIFT, A.M., M.D.,

NEW YORK,

ASSISTANT SURGEON NEW YORK EYE AND EAR INFIRMARY.

H. M. K., age 40, painter and decorator, consulted me in September, 1907, on account of loss of vision in the left eye. Sixteen days before his visit to me he noticed on rising in the morning a fog before his left eye; up to that time he had had no trouble with his eyes.

Upon examination: O. D. V., 20/20; O. S. V., 20/200 unimproved; visual field of left eye contracted concentrically 20°, relative scotoma of lower half of field.

Externally both eyes were normal; in the right fundus a mild neuroretinitis was present, limited to the temporal edge of the nerve head, extending slightly into the retina, and consisting of a blurring of the disc outline by a grayish white exudation with a few small hemorrhages on the disc and in the retinal tissue. Macula and vitreous were normal. In the left fundus were a general retinal edema and congestion of the retinal veins. The disc outlines were clouded by a grayish white infiltration which extended into the retina, particularly toward the region of the macula lutea. About the fovea small white spots of exudation were arranged like a crown. Many small and variously shaped retinal hemorrhages were scattered over the fundus, particularly around the posterior pole.

This was so similar to the classical picture of albuminuric retinitis that a diagnosis of Bright's disease was made from the ophthalmoscopic findings. The urine was found, however, to be normal and remained so upon several reexaminations. The patient never had had any serious illness. He gave a negative rheumatic and luetic history, and no stigmata of the latter disease were found upon his body. There were no headaches, past or present. Heart, lungs, arteries, and other organs were normal. No significant personal or family history was obtained. The urine at no time showed excessive indican and the blood contents were normal. Tobacco and alcohol were used in moderation. Though a painter and decorator by profession, he handled no paints himself. He had, however, for the first time in many years, a few days before the onset of ocular symptoms, mixed with his bare hands a large amount of white lead. No constipation followed this and no abdominal cramps, but at the time of my examination he displayed a faint blue line on his gums.

The patient was advised to stop work immediately. His diet and hygiene were regulated strictly, alcohol and tobacco being interdicted. He received the usual magnesium sulphate treatment for acute lead poisoning, followed by potassium iodide, which was begun at ten drops of the saturated solution three times a day and increased by ten drops daily till he was taking sixty drops t. i. d. In one week the right fundus was cleared up entirely and the vision of the left eye was 20/70, much of the exudation having been absorbed. The left eye improved rapidly until at the end of six weeks the vision was normal, the infiltration and hemorrhages having been absorbed.

At the present time, one year after discharge of the case, the vision of the right eye is 20/20 and the fundus normal; the vision of the left eye, 20/20, with outline of visual field normal. Strice of connective tissue infiltrate the nerve head and atrophic patches remain about the macula. The patient complains of the relative scotoma over the lower half of the visual field of the left eye, through which objects appear as "through breath upon a window pane."

147 East Eighteenth Street.

TRANSFUSION OF BLOOD FOR PERNICIOUS ANÆMIA

By ROBERT LUCY, M.D.,

GUELPH, ONT.

Mrs. McK., age 33, came under my care January 29, 1907. Her family history was good. She had given birth to three children, with normal labors, and had been in good health until December, 1906, when symptoms of abscess of the right kidney appeared, with frequent and painful urination. On February 13 I opened and drained the kidney abscess; examination failed to disclose any tubercle bacilli. She was discharged cured on April 13. At this time her general appearance was that of good health. She remained in good condition until January, 1908, when she again became pregnant. Three months later anemia developed and on July 31 she again placed herself in my care. Her appearance at this time was that of one suffering from pernicious anemia, with great dyspnea and swollen face and limbs. A living eight-months child was born on August 5, with no loss of blood or sepsis. The anemia and distress grew rapidly worse. The blood count showed 1,800,000 red blood corpuscles; hemoglobin 35 per cent.; megaloblasts present.

Repeated blood examinations showed a condition of pernicious anemia, which diagnosis was confirmed by several physicians, and in spite of all treatment death appeared imminent. On August 13 the husband's right radial artery was connected with the patient's median basilic vein, and blood allowed to flow for 70 minutes. On August 14 her condition was better, with less vomiting and dyspnea, and on the 15th she developed an appetite and ate a good breakfast. Color returned to the nails and underneath the tongue, and from this time on improvement was very rapid, and she was discharged in good health on September 15. An examination of the blood count taken on October 4 showed the red blood cells 3,200,000, with hemoglobin 85 per cent., no megaloblasts. According to later reports her health is perfect.

February 16, 1909, patient wrote to me, "I am enjoying the best of health."

Hydatid Moles.—G. Durante says the hydatid mole is due to imbibition by the villi, with active hyperplasia of the syncitium, dependent on obliteration and complete disappearance of the fetal capillaries in the villi. Hypernutrition and hyperplasia of the syncitium occur and vesicles are formed by accumulation in the villi of those products of the maternal blood which should go to the fetus.—*Bulletin de la Société d'Obstetrique de Paris.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, March 6, 1909.

A RETROSPECT.

THE present issue of the MEDICAL RECORD is No. 2000, not an unseemly age for a medical journal, even though reckoned in weeks instead of years, and one that invites to a little retrospection. The journal was established March 1, 1866, more than two thousand weeks ago, for it began as a semimonthly publication. Its first number was a paper of 24 pages, 8½ by 5¾ inches in size, and contained original articles, hospital reports, society reports, descriptions of new instruments, reviews, abstracts of articles from foreign journals, news, and editorial articles. The contributors of original articles to this number were William H. Van Buren, Gurdon Buck, Austin Flint, Alfred C. Post, and T. Gaillard Thomas, of this city, and E. Williams of Cincinnati—a goodly list of great names, showing that from the first the MEDICAL RECORD has been the favored channel through which the leaders of the profession have addressed their colleagues. In his salutatory Dr. Shrady set forth the aim of the new periodical. "Its object," he wrote, "will be to present to the profession a faithful record of the existing state of medical science in every one of its many departments; and, as it is more especially intended to meet the wants of the general practitioner, all the different articles published in its columns will be thoroughly practical in their character. With a wide field and ample facilities for working it up, we earnestly hope to fulfill to the letter this part of our design, thus making the RECORD worthy of the countenance and support of the profession, a journal to which they may at all times look for information, instruction, and edification. The current medical topics of the day will be freely and independently discussed, and no effort on our part will be spared to render ourselves well informed with reference to them, in order that we may be able to present such views to the profession as a body as shall be considered worthy of serious attention on their part. In all this our simple aim shall be after truth; committed to the interests of the profession as a whole, it shall be our constant endeavor to keep the columns of the RECORD free from any element that may savor of cliqueism or party spirit; and in the discussion of all subjects, great and small, to exercise that spirit of charity and honesty which must always attach itself to the side of truth and commend itself to the sanction of every independent thinker."

How well the MEDICAL RECORD has fulfilled the promise then given we must leave to others to say, but it will perhaps be interesting to note a few of the most important discoveries and advances in medical knowledge and practice which, true to its name, this journal has recorded.

The greatest and the most revolutionary discovery of these past 43 years is, of course, that of the cause of infectious disease. Four years before the MEDICAL RECORD was founded Pasteur had established his theory of fermentation and was led by the apparent similarity of the course of an infectious disease to the process of fermentation to regard the two as of essentially the same nature. Lister, in 1867, published his first article on antiseptic surgery, acknowledging his indebtedness to Pasteur, whose germ theory of putrefaction had given him (Lister) the hint from which his own antiseptic system was worked out. It required, however, many years of patient work before these principles were adopted and the science of modern surgery came into being. In 1872 Abbé announced the discovery of the immersion lens, whereby the power of the microscope was so vastly increased, and between 1871 and 1875 the process of anilin staining was developed by Weigert. These two discoveries were necessary preliminaries to the development of the science of bacteriology. In 1873 Obermeyer discovered the spirillum of relapsing fever. Neisser discovered the gonococcus in 1879, and Hansen the lepra bacillus about the same time, and, finally, in 1882, the tubercle bacillus was discovered by Koch and the malarial parasite by Laveran. In 1884 Metchnikoff observed the process of phagocytosis, and in 1897 Ehrlich published his sidechain theory of immunity. In the meanwhile, without the aid of a satisfactory explanation, such as that of Ehrlich, Behring and Kitasato succeeded in 1890 in immunizing guinea pigs against tetanus and the former made his discovery of diphtheria antitoxin which was in a few years to rob childhood of one of its greatest terrors. In 1890 Koch announced his discovery of tuberculin, a piece of news which the MEDICAL RECORD was the first to publish in its cabled report of the Berlin Congress. This was the eighth international medical congress, the first having been held at Paris in 1867, the year following the establishment of this journal, so that the history of all these meetings may be written from our pages. Beginning with the Berlin Congress, the MEDICAL RECORD has regularly published cable reports of the proceedings of these triennial meetings of the medical men of the world.

Space forbids a recounting of all the other great facts of medicine recorded in our pages, and we can only mention, as among the most noteworthy, the Esmarch method of bloodless surgery introduced in 1873; the production of local anesthesia by means of an ether spray (B. W. Richardson) in 1866, and of cocaine (Koller) in 1884; Roentgen's discovery of the *x*-rays in 1895; the confirmation in 1900 by the U. S. Army medical commission of Finlay's theory of the mosquito transmission of yellow fever, and the freeing of Havana from its century old endemic of this disease by Gorgas's practical application of the discovery; and, finally, the establishment of the first training schools for nurses in 1873 in New York, New Haven, and Boston.

For two years after its foundation the MEDICAL RECORD was issued semimonthly, but beginning with the issue of January 2, 1875, it was changed to a weekly and has so remained, except during the meeting of the American Medical Association in New York, in 1880, when a daily edition was issued. In 1873 the increase in the number of pages in each number necessitated the division into two volumes in the year, beginning, as at present, with the first numbers in January and July. With the beginning of volume 23, on January 6, 1883, the page was increased to its present size, and we may state, though the two facts are not related, that the present editor became a member of the editorial staff in the same year. For over thirty-six years the MEDICAL RECORD was edited by Dr. George F. Shrady; he retired and was succeeded by his former associate editor in August, 1904. Two of the first members of the editorial staff were Drs. John Shrady and D. B. St. John Roosa, and among others who rendered valuable editorial assistance at one time or another during Dr. Shrady's incumbency were Drs. T. E. Satterthwaite, C. L. Dana, Wesley M. Carpenter, E. C. Wendt, C. W. Allen, O. C. Ludlow, and Aimée Raymond Schroeder.

At the close of the first volume Dr. Shrady reviewed the work that had been accomplished during the year, and with the publishing of the 2000th number we can but repeat what he then wrote: "A few words concerning the journal proper will not, we trust, be out of place at this time. We have the gratification of assuring our patrons that the RECORD is in every way a success. We are in no danger of shocking our modesty by such an assertion, as its claims for favor have rested upon the aid which its numerous friends, by their valuable contributions, kind suggestions, and judicious criticisms have given it. In its management it has been our aim to be strictly impartial, and every consideration has been second to that of ministering to the more pressing wants of the daily practitioner. If we have in any respect failed in this endeavor it has been more an error of the head than of the heart. Our duties to our readers rendered it incumbent upon us to furnish the best available material, in the shape of contributions, from the most competent men. It is pleasant for us to think that in this regard at least we have discharged these obligations."

THE FUNCTIONAL ORGANIZATION OF THE CELL.

THERE is hardly any necessity nowadays to lay stress upon the great progress in the theory and science of immunity which can be directly traced to the influence of Paul Ehrlich's work and to his side-chain hypothesis of the functional organization of the cell. He conceives the cell to be a complex mechanism consisting of a number of subordinate chemical groups that serve to store and release energy under certain definite conditions of life. A number of these groups maintain the life and the special character of the cell under the usual conditions, while numerous others begin to functionate only under abnormal circumstances such as those of disease. The latter side-chains or receptors are either preformed in the cell or may be produced as the necessity arises, and it is the stimulation of the cell by the presence of toxins that leads to their overproduction and their appearance free in the body fluids in the shape of antibodies or antitoxins. This overproduction of the receptors has formed the central point of the side-chain theory of immunity and is founded upon the well-known fact much emphasized by Weigert that the regenerative impulse in the living organism is usually in excess of the immediate requirements of the organism and leads to the appearance of many more cellular and other elements than is required at the moment. However a number of phenomena in immunity could not be explained by the appearance of free receptors in the tissue fluids, and in his recent Nobel lecture, published in the *Münchener medizinische Wochenschrift* for February 2, 1909, Ehrlich takes up one of these phenomena observed in his study of the trypanosome infection. He has found, namely, that trypanosomes removed from the blood of an ape and reintroduced into its blood after the remaining parasites had been destroyed by chemical remedies were not affected by the antibodies resulting from the infection serum, but produced a disease different from the usual one only in the increased length of the incubation period. These trypanosomes therefore appeared to have become "serum-fast," as Ehrlich terms it; like changes in trypanosomes could be produced by treating infected animals by doses of medicines sublethal for the trypanosomes infecting it so that a number of them escaped destruction. Further observation showed that this change in the functionating groups of the trypanosome was a permanent one and, what is more important, was transmitted from generation to generation though it was only an acquired and not a normal characteristic of the parasite.

Ehrlich's explanation of this phenomenon is very interesting. He divides the "nutriceptors," or the functionating chemical complexes of the organism, into three groups, the first of which assimilates the simplest elements necessary for the life of the cell and is not produced in excess of the requirements of this assimilation; the second is more complex and undergoes hypergeneration in the presence of substances for which it has affinities, such overproduction resulting in the appearance of free antibodies. The third and last group, on the other hand, disappears under certain circumstances: the result of this is that the cell in question loses certain affinities and reactive powers previously evident in its processes of life. The loss of the reaction with the antibodies of the serum of immune animals is an example of such disappearance of receptors. Further experiments led to the conclusion that such artificially produced changes in the properties of the parasites could be caused not only in connection with the antibodies of immune sera but likewise toward the various specific substances which have proved to be destructive for the trypanosomes infecting an animal organism. These changes in the avidity of the organisms for various substances are conceived by Ehrlich to be in the nature of chemical phenomena, which is quite in line with his

interpretation of the whole life process of the cell as carried on by a complex of functionating chemical groups.

The importance of this addition to the theory of immunity is quite evident, for with a working hypothesis accounting for more phenomena of immunity, further intelligent experimentation with the application of the results to human therapy may be expected. Moreover, Ehrlich sees in the results obtained by him not only an explanation of the action of the various protective and curative substances produced in the living organism but likewise a clue to the workings of drugs, to their failure and their successes in special conditions. Specific chemical therapy quite comparable with the specific antitoxic therapy is Ehrlich's great aim and the clearing up of the phenomena of immunity in experimental work is an important step in this direction.

THE MODERN SCIENCE OF SANITATION.

All who had the good fortune to hear the address delivered as the opening lecture in the series being given at the College of Physicians and Surgeons upon the so-called public health movement must have been impressed by the contrast afforded in Dr. Sedgwick's historical review of the rise and significance of sanitary science. In these days when fancies are being so frequently crystallized into facts by the scientific investigator that the world scarcely halts long enough to catch their true meaning, it is refreshing to recall the oft-mentioned "good old days," which, shorn of sentiment, are not to be regretted. Knowledge of the laws of health and their application so that the greatest good shall accrue to the greatest number are scarcely a century old, yet we see the desolate places made habitable, the dread scourges of pestilent disease nearly wiped from the face of the earth, and civilized mankind everywhere becoming emancipated from the early harvest of death.

One need go back only to the age of Milton to behold a most sorry spectacle. Filth abounded everywhere, the streets were paved with slime, rushes, and the bodies of dead animals, and robbers infested the highways everywhere. It is recorded that the noxious odors from the Fleet ditch in London were so potent that they overcame the incense wafted on the air from the many churches and cathedrals along the banks. The houses were made of wood and plaster, mostly a sort of mud paste, and had roofs woven of straw and weeds. Floors were simply the natural soil impregnated with the urine of domestic animals. Under such conditions it is, of course, not at all remarkable that infectious diseases were everywhere rampant, and numbered their victims not by hundreds but by thousands. Typhus fever, leprosy, smallpox, and various malignant skin diseases were in evidence everywhere. When an epidemic broke out in a community it was considered an act of Providence to punish the people for their sins, and was so accepted.

Following out the pioneer work of Sir Christopher Wren, who was the first man of science to study the problems of ventilation in public buildings, we note that public health officers were first appointed in the latter part of the sixteenth century. Their duties were meagre, and the appointment to such a position was somewhat of a sinecure. But, after all, it is probable that the great plague in London did more to hurry onward the march of sanitary science than any other single agency up to the time of Queen Elizabeth. It is unfortunate that the world, like the individual, must learn its lesson from some great calamity.

But what is the significance of these facts in the light of present day knowledge? Simply that we are slowly but surely learning the laws of health and disease and are constantly making strides in the prevention of human misery. Everything that is ugly and repellent to our senses is a perversion of Nature, and it is by assisting Nature in her effort to produce the best that the physician finds his great opportunity. Prevention is fast becoming the chief weapon in the doctor's armamentarium, and to this he must increasingly direct his time and energy.

Fat-splitting Ferments in Lymphocytes.

It is well known that the leucocytosis which attends many infectious diseases differs much in character according to the nature of the infecting organism. Thus, pyogenic organisms and the pneumococcus call forth a polynuclear leucocytosis, while as a rule the typhoid bacillus, the excitant of syphilis, and often the tubercle bacillus cause a relative or an absolute increase in the lymphocytes. It is also quite probable that the so-called physiological leucocytosis that occurs after meals varies in character according to the food taken. Excess of proteid food is said to cause an increase in the polynuclear forms of white blood cells, while a fatty diet results in an increase in the number of lymphocytes. This latter observation has led Bergell to consider the possibility of some relation between the nature of the infecting bacillus and the character of the leucocytosis because of the existence of some ferments in the leucocytes that are best adapted for combating the special infecting organism. Müller and Jochmann have proved that polynuclear leucocytes contain a proteid-splitting ferment and the significance of this substance in attacking the proteids of the bodies of bacilli may be well imagined. In the *Münchener medizinische Wochenschrift* for January 12, 1908, Bergell communicates his experimental studies with lymphocytes which make it quite probable that these white blood cells contain fat-splitting ferments; when the existence of some fatty capsule about tubercle bacilli is remembered a teleological explanation may be had for the appearance of these cells in the blood of tuberculous patients and about local foci of infection. The experiments were quite simple, consisting in the exposure of various solid fats and waxes to the action of lymphocytes obtained from tuberculous foci. The formation of distinct depressions in the fat was evident after a few hours' exposure of such material to the action of these cells at the temperature of an incubator. It was also shown that the fat-splitting ferment was not destroyed by death of the white cells for temperatures that surely resulted in the death of cells did not do away with the chemical changes in the fat. Bergell's results, then, furnish still another cor-

roboration of the well-grounded theory which interprets all phenomena of inflammation in the light of a protective reaction to the effects of the excitants of disease, the nature of the reaction being adapted in each case to the character of such excitant.

The Effect of Baths Upon the Heart

The effects of warm and cold baths upon the size of the heart have been discussed a great deal in connection with numerous attempts to explain the curative action of such mechanical methods of treatment as the Nauheim cure, and lately the orthodiagraphic method of measuring the dimensions of the heart proposed by Moritz has enabled observers to determine changes in this respect quite accurately. Rudolph and Beck have studied by this method the changes produced in healthy and diseased persons by the administration of cold and hot baths, and now report their findings in the *Münchener medizinische Wochenschrift* for January 26, 1909. All patients subjected to these experiments had the size of their hearts measured immediately before the baths, and the operation was repeated as soon after the bath as circumstances permitted, the time between the end of the bath and the estimation of the changes in the heart not exceeding two or three minutes. The results obtained were quite uniform. The effect of the hot bath was to diminish the size of the heart, the amount of the change being quite considerable in most cases. In one case the heart remained unchanged in size. The effect of the cold bath was to increase the size of the heart, no change being noticed in one case only. The diminution in the size of the heart after hot baths was accompanied by an increase in the rapidity of the pulse and in the supply of blood to the skin, phenomena which are, of course, commonly observed after hot bathing. Cold baths, on the other hand, were followed by increased pallor of the skin and diminution in the frequency of the pulse. The limited number of cases examined does not allow final conclusions to be drawn, but the uniformity of the results obtained speaks for the correctness of the findings. Whether the therapeutic indications for the use of cold and warm baths will be modified by the discovery of these changes in the dimensions of the heart with the different temperatures of the water remains to be seen.

News of the Week.

Model Tenements for Tuberculous Patients.—The tuberculosis problem is to be approached, from a fresh side and in a most practical way, by the building of model tenements to house sufferers from the disease. Four such tenements are to be erected shortly on the east side of New York, on the block between Seventy-seventh and Seventy-eighth streets, and Avenues A and B, under the direction of Dr. Henry L. Shively, head of the tuberculosis clinic of the Presbyterian Hospital. The work has been made possible by the generosity of Mrs. William K. Vanderbilt who will spend one million dollars in the erection of the tenements. Architecturally the buildings will be notable in that they will combine the several ideas for the hygienic housing of tuberculous patients which have already been developed, and will offer many of the advantages of the sanatorium without the necessity of removal from home. Each of the four will be built in the form of a hollow square which will be entered by an archway from the street. The apartments will be reached by an open outside staircase, one of which will be placed in each corner, thus doing away with the dark common hallways. The staircases will extend to the roofs and there will thus be no necessity for fire escapes on the fronts of the houses. This in turn will permit of the building of large balconies, large enough to be used as sleeping or eating quarters, which will be connected with the rooms by windows which can be opened from the floor to the ceiling. The roofs will also be utilized to encourage outdoor life. They will be fitted with covered loggias open except to the north side where they will be protected by a glass screen. Interiorly the tenements will be divided into apartments of two to five rooms, and together will house from 350 to 375 families. Each apartment will contain either a tub or a shower bath, and will be equipped with a gas range to do away with the dust from ashes. The new buildings will be only four blocks from the new site of the Presbyterian Hospital and will be closely associated with the work of that institution.

Open Air School.—An open air public school for tuberculous children has been opened on the roof of the public library in Franklin Square, Boston, the experiment being conducted under the direction of the Boston Association for the Relief of Tuberculosis. The course of study mapped out for the children is the same as that for normal pupils in the same grades. The children are kept on the roof from nine until five daily, each child being provided with a heavy ulster and a cloth bag.

Legislation on Tuberculosis Sanatoriums.—The Wood bill, amending the law prohibiting the establishment of tuberculosis sanatoria in towns without the consent of the town board and the board of supervisors, has been reported as a committee measure. Under the provisions of the Wood bill, the person, association, corporation, or municipality proposing to establish such a hospital, files a petition with the State Commissioner of Health describing the character of the proposed hospital, stating the county and town in which it is to be located. The State Commissioner then fixes the date for a hearing on the petition and notices of this hearing are posted in ten conspicuous public places in the town where the hospital is to be located, at least ten days before the hearing. The State Commissioner's determination after the hearing is final and conclusive.

A bill has also been introduced providing for an appropriation of $175,000 for the enlargement of the Ray Brook State Hospital for Incipient Tuberculosis. There are at present two hundred on the waiting list of this hospital.

Chicago Fresh Air Hospital.—A step in advance in the treatment of tuberculosis was recently presaged when nine public-spirited citizens filed with the Secretary of State at Springfield incorporation papers for this hospital, to be conducted in Cook County without pecuniary profit. The Board of Directors includes Drs. Albert J. Ochsner, Ethan A. Gray, William G. Beele, Frederic A. Delano, Samuel Insull, Arthur Meeker, James A. Patten, James Simpson, and Theo. B. Wagner.

Vital Statistics for 1908.—Chicago is able to boast of having been the healthiest city of over 350,000 inhabitants in the United States during

1908. A total of 30,548 persons died during the year—1,595 fewer than in 1907—making a total rate of 14.10 per 1,000 of population. Of these deaths 7 per cent. were due to violence and 500 were suicides, an increase of 101 over the preceding year.

In New York City the death rate as already reported was 16.52, the lowest in its history. For 1907, the rate for Chicago was 15.3, for New York, 18.48, and for Boston, 19.2. These figures on the whole compare favorably with the death rates of some of the larger European cities, which were: London, 14.6; Liverpool, 19.0; Amsterdam, 13.4; Berlin, 15.4; Paris, 18.5; Budapest, 20.2; Munich, 18.1; St. Petersburg, 24.7. The population of New York City is estimated by the Board of Health to be at the close of 1908, 4,222,685, an increase of 137,250 during 1908.

In New York State, according to the Department of Health, there were, during 1908, 203,159 births, and 138,441 deaths, in both cases the males outnumbering the females by several thousands. Tuberculosis of the lungs was responsible for the greatest number of deaths in the State, 14,316; while heart disease caused 11,884; Bright's disease, 8,468; pneumonia, 8,602; diarrhea and enteritis, 9,286; apoplexy, 6,157; bronchopneumonia, 6,210; diseases of the arteries, 2,105; diphtheria, 2,315; and cancer of the stomach and liver, 2,561. There were 321 homicides and 1,506 suicides. As regards social conditions, the deaths among single persons numbered 64,324; among married persons, 45,605; among widows, 18,821; among widowers, 9,387. The deaths from old age were given as 2,502, while there were 9,342 deaths among those over eighty years of age. The total population of the State is estimated at 8,546,356.

Changes in Ambulance Service.—As had been previously announced, the emergency ambulance service which had been maintained by the Roosevelt Hospital for thirty-two years was abandoned on March 1, the managers of the hospital having decided upon this course in view of the criticisms of the service. Because of this relinquishment a rearrangement of the ambulance districts of the city has been necessary, and in the future the New York Hospital will cover the territory from Twenty-seventh to Forty-second street, while the Flower Hospital will answer all calls between Forty-second and Seventy-sixth streets. The district of the J. Hood Wright Hospital has been extended down to Seventy-sixth street. The new automobile ambulance recently delivered to Bellevue Hospital is to be sent to the Fordham Hospital district, which extends as far as City Island.

Dr. L. Duncan Bulkley will give the tenth series of clinical lectures on diseases of the skin in the outpatient department of the New York Skin and Cancer Hospital, Second avenue and Nineteenth street, on Wednesday afternoons, commencing March 10, at 4:15 o'clock.

Psychiatric Clinic.—The gift of $500,000 to Johns Hopkins Hospital made by Mr. Henry Phipps of New York, for the purpose of establishing a psychiatric clinic, has been increased to more than $1,000,000, according to an announcement made at the thirty-third anniversary exercises of the Johns Hopkins University on February 22. It will thus be possible to build and equip a clinic which will not only be the first of its kind in this country, but will rank among the foremost of the world. Dr. Adolf Meyer of New York is to be the head of the new department.

Changes at Yale Medical School.—Beginning with next year, the requirements for admission to the school will include two years' work of college grade, embracing chemistry, biology, and physics. Practically all of the laboratory work will be completed in the first two years at the medical school, and the second half of the course will be devoted to clinical studies.

The College of Medicine, University of Southern California, at Los Angeles, has been transferred to the University of California. Arrangements will be made by which medical students will take the first two years of the course at Berkeley, and the last two here.

Dr. Francis Carter Wood has been appointed an attending physician to St. Luke's Hospital, New York, in addition to the appointment as pathologist which he still retains. A special service is to be created for the study of diseases of metabolism in connection with the chemical department shortly to be developed in the pathological laboratory.

Dr. Charles Jewett is about to retire from the presidency of the Bushwick Hospital of Brooklyn, N. Y., an office which he has held since the incorporation of the hospital. His resignation is due to increasing demands upon his time in other lines of work.

Professor von Strümpell, director of the medical clinic in Breslau, has accepted the appointment as head of the third clinic for internal diseases in Vienna. The position has been vacant since the death of Professor von Schrötter last May. Professor von Strümpell will take up the new work in April, and will begin his lectures during the latter part of May.

Sir Felix Semon, K.V.O., who twenty-five years ago founded the *Centralblatt fuer Laryngologie,* announces in the February issue of that journal his forthcoming retirement from its editorship and his retirement as well from medical practice. He will be succeeded by Dr. George Finder of Berlin who has been the subeditor of the journal for some years. Every writer on laryngological or rhinological topics is in debt to Sir Felix Semon and to the *Centralblatt,* founded by him, which ever since its establishment has furnished each month an accurate condensation of current literature in its own special departments.

Dr. Holmes C. Jackson, at present Director of the Bender Hygienic Laboratory at Albany, has been elected Professor of Physiology and Director of the physiological laboratory at the New York University and Bellevue Hospital Medical College, succeeding Dr. Graham Lusk, who has been appointed Professor of Physiology at the Cornell Medical College.

Dr. Samuel G. Dixon, State Health Commissioner of Pennsylvania, received the degree of Doctor of Laws from the University of Pennsylvania at the Founders' Day exercises on February 22.

Harvey Society Lectures.—The ninth and last lecture in the present course of Harvey Society lectures will be delivered by Dr. C. B. Davenport, Director of the Station for Experimental Evolution, Cold Spring Harbor, New York, on Saturday, March 6, at 8:30 P.M., at the New York Academy of Medicine, 17 West Forty-third street. The subject of the lecture will be "Heredity in Man."

For Medical Research.—During the exercises in celebration of Founders' Day at the University of Pennsylvania on February 22, Provost Harrison

announced an anonymous gift of $200,000 to the University to be used for the establishment of a department of research in the medical school.

Smallpox in Mexico.—The situation as regards the number of cases of smallpox in various parts of Mexico shows no improvement, and the disease has been reported also from Huichapan, where several cases of black smallpox are said to have appeared.

Cholera in St. Petersburg.—Up to February 22, when the epidemic of cholera in St. Petersburg had lasted for 160 days, 10,000 cases had been reported with 3,928 deaths. The largest number of new cases reported in one day was 444, the lowest nine.

Gibb Operating Pavilion.—The new operating pavilion on Blackwell's Island, New York, was opened on February 25, in the presence of about 300 guests. Blackwell's Island, with its 3,000 inhabitants, has suffered from the lack of operating facilities, and the new pavilion, which has been erected at a cost of $24,000, will be greatly appreciated. It has been named the Gibb operating pavilion in honor of Dr. W. Travis Gibb.

American Academy of Medicine.—The second mid-year meeting of this society will be held in Chicago on March 25, 1909, being a conference with academic and medical teachers. At the evening session the question, "What Constitutes a Liberal Education in the Twentieth Century?" will be discussed by the presidents of the State University of Iowa, Knox College, and Western Reserve University. At the morning and afternoon sessions questions of medical education will be considered. Further information may be obtained from the Secretary of the American Academy of Medicine, Easton, Pa.

Deaths of Centenarians.—Mrs. Mary Niemann, a native of Poland, died in the Luzerne County Almshouse at Wilkesbarre, Pa., on February 12, at the alleged age of 112 years. Mrs. Minnie Topp died in Pottsville, Pa., on February 19, at the age, also alleged, of 102 years.

Complaint Against Alleged Laxity.—A committee from the Illinois State Medical Society has presented to Governor Deneen a complaint against the Illinois State Board of Health, based on the alleged lax system of examining applicants for physicians' licenses in that State.

State Reservation at Saratoga Springs.—A bill has been introduced into the present Legislature, providing for the creation of a State Reservation of all the mineral springs and gas well properties in the town of Saratoga Springs. The act provides for the appointment by the governor of three commissioners, to acquire the land, after which acquisition the springs shall be open and free to the public. The measure has the endorsement of the State Medical Society and the Saratoga Springs Medical Society, the latter pointing out that unless prompt action is taken the springs may be entirely depleted owing to the establishment near the village of five gas well corporations which extract from some sixty bored wells, from 700 to 1,000 cylinders of liquefied carbonic acid gas at 1,000 to 2,000 pounds pressure per day. This has already greatly lowered the water level of the springs.

Surgeon Recovers Fee.—In the Supreme Court of New York, Part 14, on February 11, after a jury trial lasting two days, a surgeon of this city obtained a verdict against another medical man for performing an operation for appendicitis upon his wife. It was admitted that the defendant had retired from practice, and was therefore not entitled to professional courtesy, the only question for the jury to decide being the reasonable value of the services. Every expert, with the exception of one general practitioner, estimated the value of the services to be from three to five thousand dollars. The surgeon's bill was for $3,650. The jury's verdict was for $2,325 and costs.

Semicentennial of the College of Physicians and Surgeons.—The Alumni Association of the College of Physicians and Surgeons celebrated the fiftieth anniversary of the school by a dinner at Sherry's, on Tuesday evening of this week. Speeches were made by the Dean, Dr. Samuel W. Lambert, President Nicholas Murray Butler of Columbia University, the Rev. William R. Richards, Dr. Henry A. Christian, Dean of the Harvard Medical School, Seth Low, the former President of Columbia, and Dr. William M. Polk.

Plan to Rescue Dr. Cook.—The Arctic Club of America is preparing to equip an expedition to search for Dr. Frederick Cook of Brooklyn, who is supposed to be wintering somewhere in the polar regions after an attempt to reach the pole last summer. Dr. Cook started for the pole in June, 1907.

Major Carroll's Widow.—An appeal has been sent out of the office of the Surgeon-General at Washington, to all army medical officers, asking for contributions to relieve the distress under which the widow of Major James Carroll is placed. Major Carroll, as is well known, died as the results of the investigation into the etiology of yellow fever, in which he was associated with Drs. Walter Reed, Jesse Lazear, and Aniticles Agramonte.

The International Opium Conference, which has been in session at Shanghai, China, since February 1, held its final meeting on February 26, when the reports of committees were submitted and passed upon. No full details of the action of the congress have yet reached this country.

London X-Ray Convention.—A convention which will include all branches of medical electricity will be held in London from July 5 to 9, 1909, at the University of London, University College. A simultaneous exhibition will include all sorts of electrical and physical apparatus for medical treatment, and one afternoon session will be devoted to the demonstration of new apparatus. Detailed information can be obtained from the organizing secretary, Ernest Schofield, 11 Chandos street, Cavendish Square, London, W.

Rochester Societies Affiliate.—The Rochester Pathological Society and the Rochester Academy of Medicine have agreed to affiliate, the society to become a new section of the academy, which shall be known as Section V, the Rochester Pathological Society.

American Laryngological, Rhinological, and Otological Society.—A joint meeting of the Western and Middle Sections of this Society was held in Chicago, February 22, 1909, in the Assembly Hall, Northwestern University Building, under the joint chairmanship of Drs. Joseph C. Beck of Chicago and R. Bishop Canfield of Ann Arbor, Mich. The meeting was well attended. The scientific program consisted of demonstration of clinical cases, demonstration of methods, anomalies of frontal sinus demonstrated by stereoscopic radiograms, microscopic slides, and exhibition of instruments. The

following papers were read and discussed: "Certain Methods of Precision for the Inflation of the Eustachian Tube and Tympanum," by Dr. Thomas Hubbard of Toledo, Ohio; "Vaccine Diagnosis and Therapy," by Dr. Robert Levy of Denver, Col.; "Anesthesia in Ear, Nose, and Throat Surgery," by Dr. Norval H. Pierce of Chicago; "The Value of Certain Operative Measures in the Treatment of the Cerebral Complications of Suppurative Otitis Media," by Dr. S. MacCuen Smith of Philadelphia; "Some Observations on the Acoustic Function of the Ear," by Ernest de Wolfe Wales of Indianapolis; "Extralaryngeal Causes of Laryngeal Symptoms," by Dr. Frank Smithies of Ann Arbor, Mich.; "Lamentable Accidents Occurring in the Practice of the Otolaryngologist," by Dr. J. A. Stucky of Lexington, Ky.; "Concerning Labyrinth Suppuration," by Dr. L. F. Page of Indianapolis, Ind.; "Obstinate Stenosis of Laryngeal Diphtheria; Notes of Progress and Treatment of Two Cases," by Dr. D. J. Wishart Gibbs of Toronto, Ontario.

Obituary Notes.—Dr. Joseph Huber of New York died in the Lebanon Hospital on February 22 of edema of the larynx. Dr. Huber, who was fifty years of age, was graduated from the College of Physicians and Surgeons in 1888, and later served as interne at the German Hospital. He was a member of the New York Academy of Medicine.

Dr. William McCollum of Brooklyn, N. Y., died at his home on February 23 of acute bronchitis and pulmonary edema, aged 76 years. Dr. McCollum was graduated from the Castleton Medical College of Vermont in 1853, later taking a postgraduate course in the College of Physicians and Surgeons, New York. He was an honorary member of the State Medical Societies of New York and Connecticut, and a former president of the Vermont State Medical Society and of the Kings County Medical Association, and vice-president of the Medical Association of Greater New York. During most of his professional life he was a contributor to leading medical journals.

Dr. John W. Atwood of Fishkill Landing, N. Y., died at his home on February 21. He was a graduate of the Jefferson Medical College in the class of 1888, and was a member of the American Medical Association, the State Medical Society, and the Newburgh Bay Medical Society. He was an attending surgeon to the Highland Hospital at Matteawan, and physician to the Orphans' Home.

Dr. Samuel G. Fisher died at Port Deposit, Md., on February 20, at the age of 77 years. He was graduated from the University of Maryland School of Medicine in the case of 1854. He was engaged for more than fifty years in the practice of his profession in Chestertown, Md.

Dr. Charles L. Coulter died at Philadelphia on February 23 at the age of 59 years. He was a native of Lindsay, Canada, and was graduated from the Medical Department of Victoria College, Toronto, in the class of 1875. He was at one time Chief Surgeon of the Canadian Grand Trunk Railroad and also Government Inspector of Medical Supplies for the Dominion of Canada.

Dr. Walter A. Harding of Everett, Mass., died at his home in that city on February 16, after a short illness, from pneumonia, aged 35 years. Dr. Harding was graduated from Tufts Medical School in 1899, and for two years past had held the position of assistant professor of anatomy in the College of Physicians and Surgeons of Boston.

Dr. Robert A. Murray, president of the New York Society of Medical Jurisprudence, died at his home in New York on February 27, of pneumonia, after a short illness. Dr. Murray was born in New York, in 1852, and was graduated from the City College in 1871, and from the medical department of New York University in 1873. He was a fellow of the Academy of Medicine, and a member of the American Gynecological Society, the New York Obstetrical Society, and the American Medical Association. He was also consulting gynecologist to the French Hospital and associate surgeon at the Woman's Hospital.

Obituary.

FREDERIC IRVING KNIGHT, M.D.

BOSTON.

Dr. Frederic Irving Knight of Boston died suddenly on February 20 from an attack of angina pectoris. He was in his sixty-ninth year and had continued his professional duties until a very few days before his death. He was a graduate of Yale University in 1862 and of the Harvard Medical School in 1866, later studying in Berlin, Vienna, and London. He was one of the Founders and an ex-president of the American Laryngological Association in 1878 and had continued his activities in that society, although during recent years he paid special attention to chest diseases and was prominently engaged in the tuberculosis crusade in his own city. He was also an ex-president of the American Climatological Association. During his earlier years he was one of the Harvard instructors in nose and throat as well as chest diseases. Dr. Knight was representative of the best ideals of the medical profession. He was a writer of great acumen and clearness and made many valuable contributions to literature. He was a man of wide culture and the charm of his presence was always manifest.

Correspondence.

THE EMMANUEL MOVEMENT AND ITS RELATION TO THE MEDICAL PROFESSION.

To the Editor of the Medical Record:

Sir:—Do the leaders of the medical profession in Boston lead? If they do, into what are they leading the profession? The medical profession of New England has been watching with breathless interest the combination of magic, Mesmerism, medicine, and religion which has gone under the name of the Emmanuel movement. Their interest has been intense, for upon the outcome of this movement will rest the whole advance which they fondly believe has been made in medicine. If this method which has been the most thoroughly tried and the most thoroughly discredited of any method which has ever been practised for the alleviation of human suffering, is with the help of modern psychology to become the best recognized method of treating a large class of diseases (and how large the class is no one knows, for there are confident assertions that it will include all those diseases which were treated by the Savior and will even outdo the work done by the apostles), then it is time that the medical profession takes some means to perfect itself in its technique. So far, the actual treatment has been done very largely by the clergy, but now it seems that the leaders of the profession in Boston are to take it in hand and see to it that only proper patients are treated. The following from the *Boston Daily Globe* of January 28, 1909, is of interest in this connection:

"The advisory board of the Emmanuel movement, composed of Drs. Joel E. Goldthwaite, Richard C. Cabot, James G. Mumford, and Joseph H. Pratt, have drawn

up a set of rules which are designed to avoid some of the earlier mistakes made by the clergy among that class of patients who have no family physician. These well-known physicians, according to their signed statement, believe in the Emmanuel movement, but are also of the opinion that methods different from those now practised are necessary to bring the movement into closer relationship with the physicians. The rules have been adopted by the clergy in the Emmanuel movement in Boston, who yesterday issued the following statement:

"'In order to preserve and extend the cooperation of the physicians and ministers the following rules have recently been adopted by the Emmanuel clergy:

"'1. No person shall be received for treatment unless with the approval of and after having been thoroughly examined by his family physician, whose report of the examination shall be filed with the minister's records.

"'2. No patient shall be referred for diagnosis or treatment to any specialist or assistant save with the advice and consent of the patient's own physician.

"'3. All patients who are not under the care of a physician must choose one and put themselves in his care before they can receive instruction at Emmanuel church To those who ask for advice in this choice there shall be handed a printed alphabetical list of all the general practitioners (internists) attached to the visiting and outpatient staffs of the Boston city hospital, the Carney hospital, the homeopathic hospital and the Massachusetts general hospital.

"'From this (or from any other source if the patient prefers) a physician is to be selected. Should these physicians decide that none of the patients thus referred to them ought to receive treatment at Emmanuel none will be treated there. Through the operation of Rules 1, 2, and 3 it will be seen that an internist remains throughout in general charge of every case. It thus rests wholly with the physicians of this community and not with the Emmanuel clergy to decide whether or not a patient should be referred to a neurologist or other specialist, and which, if any, are suitable for treatment by moral and religious reeducation at Emmanuel. We believe that under these rules the fundamental object of the movement deserves the support of all physicians and of the community generally.'"

"These well-known physicians," according to their signed statement, "believe in the Emmanuel movement," but we have as yet seen no reasons given for their belief and it would be interesting to learn from them what class of cases they think suitable for this method and the reasons why they believe this treatment to be better than their own. This appears highly important as an index to the family physician, for it is hardly reasonable to ask him to pass final judgment on every case which may be attracted by newspaper notoriety when he has had but limited experience with similar methods, and that generally of an unsatisfactory character. If a patient comes who has no family physician, or what is more likely, whose family physician refuses to be a party to any such transaction, then the patient is to be given a printed list of the physicians who are connected with the large hospitals and they are to choose a physician "from the list or from any other source." Here again the physicians from the hospitals "or from any other source" are in the same dilemma; their training has been along entirely different lines and how are they to advise intelligently these would-be patients?

Personally, I have never been able to see, except in details, any difference between the magic used by savages, Braidism, Mesmerism, hypnotism, Perkins' tractors, and the present movement. I am willing to grant that the present method makes a more intelligent use of modern psychology, but psychology is largely an explanation of why certain mental conditions or sensations result from certain excitants. It has not, as I understand it, created any new sensations or methods of treatment, but rather it has explained these already known. It is most satisfactory to know why people act in certain ways, but it may be open to question whether it helps the people or makes them act any differently even if we do understand.

The Indian medicine man who beats his drum and shakes his rattle to make good medicine accomplishes the same result as the man who understands and uses modern psychology. He does not understand the result, but he understands the method and accomplishes as much as, if not more than, has ever been done among civilized people

It has been the custom in the past at the annual meeting of the Massachusetts Medical Society to show the members new operations, new methods of treatment, interesting cases from the great hospitals of Boston; in fact, to show what the local profession had done during the past year. I wonder if the Emmanuel movement will be one of the objects of interest exhibited next year? How does this compare with the work done by Fitz, Shattuck, Putnam, Mixter, Richardson, Harrington, Munroe, Rotch, and a score of others? The physicians of Massachusetts in the past have done valuable work for the relief of humanity and they are respected by their fellows for their work. "By their fruits ye shall know them," but what will the harvest be" of this short cut which casts aside the work of the past and easily and gracefully floats the patient through the pearly gates of a New Jerusalem of Health?

CAROLUS M. COBB, M.D.
BOSTON, MASS.

FOOD PRESERVATIVES.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—It is possible that there are some medical men who are not familiar with the well-established fact that heat can sterilize any kind of organic material. Whether dirty or rotten, clean or fresh, good or bad, makes not one particle of difference to the power of heat in this direction. Once such material is sterilized by heat and sealed from the air it will keep indefinitely. There is not a particle of difference in the keeping qualities, while sealed, of any sterile organic substance. This fact can be verified by any person who cares to go to the trouble of a trial, and he can likewise discover that there are not two opinions of the truth of the matter if he will ask any educated bacteriologist about it. Since, then, there is absolutely no difference between the keeping qualities of pure or impure, clean or dirty, sterile, sealed goods, what means the controversy over the keeping quality of catsup? It is simply this: Can a sterile bottle of catsup keep fresh for, say, a week after being opened when it contains no preservative? Here is the whole issue in a nutshell. No one who knows anything about the subject under discussion denies the keeping power of catsup containing no preservative, while it is under seal. What is denied is that any living person can manufacture such an article and have it keep *after being opened* and under use for more than a day in warm weather. All the experience of all the canners in the world proves that sterile provisions will keep indefinitely without preservatives if kept sealed from the air. All the experience of every housewife proves that such goods quickly spoil after being opened, unless they contain a preservative. The sole issue is on the keeping of the goods *after opening*.

In view of these facts, is it asking too much of Mr. Pierce when I request him to supply the readers of the MEDICAL RECORD with such evidence as he may have of the truth of the extraordinary statements he makes in his communication which appears on page 321 of your issue of February 20? Will he tell us where to find one or more of the "expensive factories" for the utilizing of garbage from the floors of canning factories? Will he give us some evidence of his statement that such garbage is converted into "catsup, soup, apple-butter, jam, and mince meat"? Perhaps he will be willing to describe the way this wonderful miracle is accomplished? Perhaps he will be willing to let us know how or why it is that the users do not know enough to use heat in sterilizing such stuff just as heat is used in sterilizing the best of stock? It would be interesting to know why they choose to throw away their money in so senseless a manner. It may be interesting to him to learn that as partly decayed substances contain products of decomposition they require less preservative to keep them, after exposure to the air, than do fresh goods. It is the fresh goods that need the most preservative after exposure to the air. Of two sterile cans of any kind of food to which no preservative has been added, and that have been opened and exposed to the air, the one prepared under dirt and decomposition will keep the longest. It contains aromatic products of bacterial decomposition and these protect it. Neither needs any preservative until opened.

Mr. Pierce is not unknown to the medical profession as a man of lurid words, when writing about pure food. It is not long since he was called to order by the editor of the *Journal of the American Medical Association* for "out-Heroding Herod." This was on page 1454 of the issue of May 6, 1905. Another medical editor got after him for exaggeration at about the same time. This the reader will find in an editorial in *American Medicine*, page 676, of the issue of April 29, 1905. This last-named editor informs us that Mr Pierce had been

telling the American public that canners were utilizing "old horses and mules, seaweed, old boots, and shoes; and the 'gleanings from the sewers' are utilized, he says, to 'appease the seeming hunger for the lower grade of goods!'" The editor then went on to say: "No good cause needs such championship as that supplied by Mr. Pierce in his *Public Opinion* article." Can the reader wonder at my desire to have Mr. Pierce give us a few facts in support of his, to me, exceedingly unlikely and positively unreasonable statement?

Brooklyn, N. Y. R. G. Eccles, M.D.

THE ETIOLOGY OF COMMON COLDS.

To the Editor of the Medical Record:

Sir:—I beg to offer some remarks upon Dr. Robert C. Brown's paper on "Some Factors in the Etiology of a Common Cold," published in the Medical Record of February 6. First, I want to applaud Dr. Brown on his final conclusions that common colds are not bacteriological diseases; then I would direct attention to some errors of statement regarding the theories of other observers on the non-bacterial side. Dr. Brown states that Bosworth's and Wakefield's theories are opposed to each other, that neither has any foundation in physiology, and both are opposed to Seitz's theory, which has a foundation in physiology and is most nearly correct.

Bosworth (Diseases of the Nose and Nasopharynx, 1889) expressly endorses the theory of Seitz (Ziemssen's Cyclopædia, Vol. XVI), though he mentions its incompleteness, which is the shortcoming of all the older concepts. Rosenthal's theory is criticised by Bosworth as being too mechanical and inefficient as an explanation of all the manifestations, and it may be said here that it is principally in this respect that all the older theores vary from our own. We really simply elaborate and perfect the more primitive descriptions of the old masters by filling in the gaps which modern research achievements have made possible. In the writer's case (Medical Record, December 2, 1906) the mechanical aspect was elaborated by filling in of biochemical and metabolic knowledge of the present day. The fact of the matter is that Bosworth's and Seitz's theories are identical fundamentally. My own paper on the subject made no attempt whatever to set forth a new mechanism of the tissue reaction to extraneous temperatures, but after stating the accepted mechanism in my own language, yet not intentionally making an innovation on the classical descriptios of Seitz, I elaborated the old theory by adducing a theory of the biochemical process involved in the exsanguination of the peripheral tissues as a result of the tetanic contraction and condensation of the peripheral tissues, which occur as a tissue reaction to the external cold. The so-called reflex mechanism of the tissue reaction which exsanguinates the peripheral tissues is the original reactional manifestation. I think no one denes this reflex action as the primary reaction. Neither Seitz nor Bosworth attempted to go into the chemical or physical status of what was accomplished by the original contractions, so my work was simply an elaboration of earlier work which did not attempt to explain any but the now accepted original reaction involved. My contention that peripheral refrigeration involves condensation of tissues, as heat involves distention and expansion, does not invalidate the premise, though it does help to explain the more permanent effects of colds, not always explainable on the basis of congestion and venous stasis.

Dr. Brown observes: "Wakefield thinks that exposure to cold produces in remote portions of the system areas of suboxidation, which become inflammatory foci." Now, I have no doubt that Dr. Brown has unintentionally misquoted my article, especially inasmuch as he apparently endorses what I really set forth, though attributing it all to Seitz. My expressed contention was that when the periphery of the body is subjected to a chilling influence, the superficial tissues contract, exsanguinating the capillaries and determining the blood from the periphery to the great splanchnic venous trunks, and engorging and congesting the visceral organs. When inflammatory reaction follows, not the peripheral, but the visceral organs are prone to be its seat. I regret that space does not permit extensive quotation from my original monograph, as to how maldistribution of the blood and chemical disequilibrium results from the above causes, and how phophylaxis of pneumonia and other febrile reactions from "catching cold" may be carried out by those who perhaps in their own families at least do not care to fold their arms and await the unaltered outcome of what they believe to be inevitable parasitic processes. Homer Wakefield, M.D.

New York.

THE TREATMENT OF ERYSIPELAS.

To the Editor of the Medical Record:

Sir:—In the Medical Record of February 13, 1909, there appeared an article by Dr. Aspinwall Judd, entitled "The Treatment of Erysipelas by Means of Carbolic Acid and Alcohol." It may be of interest to the profession to know that this most efficient method of treating erysipelas as described by Dr. Judd was advocated originally by the late Dr. Seneca D. Powell, some twelve or fifteen years ago. A description of his technique appeared in the Transactions of the Southern Surgical and Gynecological Association for 1900, and is as follows:

"Erysipelas is also amenable to treatment with this drug, and here we use 95 per cent. carbolic acid, and it will be probably the most severe test that the surgeon will be called upon to make—I mean from the surgeon's standpoint. He must always follow directions closely, and damage may result from a failure to observe this. I manage it in this way: Placing the patient flat on the back, and with the head placed back so as to present as nearly as possible a level surface of the face, I apply a 95 per cent. solution of carbolic acid with a well-rolled mop of absorbent cotton. I watch the surface carefully, and as soon as it turns white I swab it off with alcohol. Your materials should be at hand and readily available, and you should depend upon your judgment as to when the alcohol should be applied, and not upon the complaints of the patient. I paint the surface about the eye with pure acid, holding gauze pledgets in between the closed lids, to prevent the acid entering the eye. Be very careful not to allow the alcohol to be brought into contact with the surface before the acid is applied, as it will prevent the acid from acting on that surface. After this, not only the entire face, but all of the surface involved by the disease can be treated is this way. You will have to use a larger mop of cotton, so as to go over the surface rapidly and completely. Then in some cases it will act so quickly as to compel you to do it in sections, not only covering the diseased surface, but going over the line one inch or more; especially does this apply to the treatment of erysipelas in other locations. I have applied carbolic acid in this way to the entire body below the nipple line and above the knees to a patient, a young girl, about twenty years of age, reducing the temperature from 106° to normal in four hours. The action of the acid in these cases is uniformly promptly successful in its results."

In August, 1900, the late Dr. A. M. Phelps, before the Thirteenth International Medical Congress in Paris, made the following statement: "The profession is indebted to Dr. Seneca D. Powell, of New York, for one of the most useful discoveries ever made in surgery. I allude to the antidotal effect of alcohol in carbolic acid. Dr. Powell has used carbolic acid for years in the treatment of infection and bone diseases in various parts of the body, and has recommended it for erysipelas and abscesses. I have tested it in the treatment of erysipelas, and find it as specific in that disease as quinine is a specific for malarial poisoning." Edward W. Peterson, M.D.

New York.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

LETTSOMIAN LECTURES—TUBERCULOSIS COMMISSION—WERTHEIM'S OPERATION—REGISTRAR GENERAL'S REPORT—FRIENDLY SOCIETIES AND THE PROFESSION—MEDICAL BENEVOLENT FUND—OXYGEN FOR ATHLETES—PRINCE OF WALES F.R.C.S.

London, February 12, 1909.

The Lettsomian lectures of the Medical Society of London are being given by Dr. Martin, who has chosen as subject the "Functional Disorders of the Stomach." These he grouped as (1) gastric irritation, (2) gastric deficiency, and (3) indigestion of nervous origin. Before dealing with the signs and symptoms of these disorders, he took a general review of the secretory activity of the stomach and of its motor power in all forms of disease. The digestive activity of the contents of the stomach was determined by the amount of pepsin secreted and varied with the amount of hydrochloric acid. In those forms of gastric irritation called acid dyspepsia, it had been shown that two hours after a meal from 0.25 to 0.4 gram per cent. of acid was secreted, but taking such cases as were admitted to hospitals with grave defects of nutrition, there was hypo- more often than hyper-chlorhydria. A large proportion of cases showed deficiency of secretory activity. Of seven cases of neurosis one had achlorhydria, two

a percentage of 0.12, one of 0.2, one of 0.24, and two of 0.29 acid. Those were cases of dyspepsia, with many nerve symptoms.

When cases were admitted there was great variability in the secretion of acid, so that it might be impossible from the symptoms only to determine whether any case was one of increased, decreased, or absent acid secretion. Generally the digestive power was proportionate to the amount of acid, but when acid was present to some amount there might be no pepsin. Organic acids were absent when the acidity was over 0.2 per cent., but below that some organic acids, chiefly lactic, were found in small amounts. In gastric ulcer there might be either excess or deficiency; in cancer more frequently a deficiency. The lecturer concluded that the results of analysis of the contents of the stomach might assist diagnosis in connection with other facts, but could not be relied upon as diagnostic.

The third interim report of the Tuberculosis Commission was issued last week. It is a blue-book of 38 pages, including an appendix. You will remember that in the preceding (second) interim the question of the danger of milk from tuberculosis cows when the udder showed no signs of disease was left undecided. This question has been taken up and careful investigations by Dr. F. Griffith made on one of the commission's farms. The results are perhaps of special importance, as they are based on observations on animals purchased when already tuberculous—not on those artificially inoculated. Six cows were obtained; in five the udder was normal, and in the sixth the disease was not detected until after death. Three of the cows were obviously tuberculous from a clinical point of view, three apparently healthy, but reacted to tuberculin. The milk of the three obviously diseased, drawn under precautions against contamination, infected guinea pigs when inoculated in small doses, though this result was not invariable. The guinea pigs were not affected by the milk of the other three. The feces of five of the cows, obtained with minute precautions, contained virulent bacilli, and was tested both by inoculation and feeding. Tuberculosis followed minute quantities inoculated by the peritoneal method into guinea pigs. In three out of six cases of young swine unaffected by the tuberculin test and fed with emulsion of the feceses in sterilized milk tuberculosis was produced. Considering that few herds are altogether exempt from the disease, the pressure at an early stage of living virulent bacilli in large quantities in the feces, it is time for English farmers to adopt strong measures against contamination of the milk, for it is well known from many reports that fecal matter is frequently found in samples of milk that were supposed to be pure. Moreover, the too common practice of giving to pigs any milk that is suspected or condemned should be forbidden under heavy penalties. The commissioners remark that cows with extensive lung disease must discharge numbers of bacilli from the air passages by coughing, and some of these may find their way into milk; but their experiments indicate that the excrement is much more dangerous. With slightly diseased cows bacilli are found in the feces, while as regards those animals which are clinically tuberculous their "experiments show that the feces contain large numbers of living and virulent tubercle bacilli."

They further insist that the presence of diseased animals in the sheds with healthy cows is distinctly dangerous and some of the bacilli are almost certain to find their way into the milk.

From this brief summary of the last report you will see how fully the experiments confirm the results obtained by investigations on your side, and which most of us have regarded as conclusive. Those who have not accepted the views thus confirmed will find it difficult to remain unconvinced.

Wertheim's operation, as it is generally called, though he only modified it, has been discussed at the Medical Society of London *à propos* of a paper by Dr. Comyns Berkeley, who gave statistics of 220 cases from different operations in the United Kingdom. He said it had a great advantage over simple vaginal hysterectomy as to operability and cures and not much difference in fatality if only similar cases were compared. The simple proceeding had a lower mortality in early cases, but the after results were often disappointing. The decision as to the best procedure depended on whether the regional glands were affected.

In England Wertheim's operation has not been performed for more than some five years—not long enough to establish the percentage of cures. Wertheim operated on 200 patients more than five years ago, and 138 are still living. Dr. Berkeley discussed several questions, including local recurrence, which he held was rare with the extended abdominal operation. He showed a pair of clamps which overcame the dangers and difficulties of Wertheim's. He also showed the specimens of 27 of the 30 which he and Dr Bonney had removed.

Dr. H. Spencer said the terrible thing about Wertheim's operation was the high mortality—24½ per cent. on the first 200 cases and 9½ per cent. on the whole 400 Wertheim had done. After vaginal hysterectomy it was only 4 or 5 per cent. It was a very grave question whether a patient with cancer should undergo such a formidable risk.

Dr. McCann considered the future of the operation was in early cases; in advanced ones he was doubtful of any operation. It was most important to insure hemostasis and cover the surfaces of the peritoneum; then subsequent infection was not probable. If the bladder was involved operation was not justifiable. He kept the patient in the Trendelenburg position as short a time as possible. He never kept a drain in more than 48 hours; indeed, it was not needful to put one in at all if hemostasis was established.

Dr. Lewers believed Wertheim's would be the future operation, not only for cancer of the cervix, but for the body of the uterus also. He had performed it on 22 patients, all of whom had advanced cancer. He lost four out of the first 10, out of the second 10 none at all. It was usually best to begin as a laparotomy, as sometimes it was impossible to complete.

Dr. Russell Andrews said his experience was similar to that of Dr. Lewers. He had few opportunities of seeing early cases. He thought as experience increased the mortality would eventually fall to that of vaginal hysterectomy.

The Registrar General's report for the year 1907 has just appeared. It is to be noted that this gives in detail the statistics and supersedes the estimates formed from the quarterly returns. The decline in the rate of increase of the population has continued. The proportion of marriages has also decreased from 108 in the previous year to 93. The birth rate was the lowest recorded, and this fact has elicited all sorts of speculation in the newspapers. From the commencement of registration in 1837 up to 1874 the registration steadily improved and is reckoned as complete from 1875. The birth rate attained the highest point in 1876, viz., 36.3 per 1,000 of the total population. Since then it has gradually fallen to 26.3. The effect of this on the increase of the population is to some extent modified by the fall in the death rate, but, clearly, this last cannot continue indefinitely.

The death rate of 1907 is also the lowest recorded and corresponds to a rate of 15.0 per 1,000, being 0.4 below that of 1906. Compared with the decennial average 1897-1906, it shows a decrease of 1.7 per 1,000. It is encouraging to observe that a break has occurred in the increase of the fatality from cancer, which has persisted so long. The rate of enteric fever is also the lowest on record. Diseases of the circulation show some increase. Measles was more fatal, but diphtheria and other children's diseases less fatal.

A conference arranged by the Charities Organization Society was held on Saturday to discuss the relations between the medical profession and friendly societies. It was opened by Dr. James Pearse, who pointed out that the profession recognized the good that had been done by friendly societies, but found that they did not properly meet the claim for sick attendance. The report of the Manchester Unity of Odd Fellows showed that the doctors received approximately 2 per week for such attendance, and complained that members of the clubs earning good incomes were not ashamed to take advantage of this attendance. He suggested that a wage limit or payment for work done should be arranged. Sir T. Smith thought it only human nature for well-to-do club members to avail themselves of the doctor's services, as every one liked to get the most for his money. Sir T. Barlow said no one class did as much for others as doctors, knowing they would get no remuneration. But the skilled artisans of the counties should recognize justice and pay their doctors more than a "mere pittance." A representative of the Odd Fellows said if they could not have the club doctor the majority of the members would go on the parish or to the local hospital. Would the doctors prefer that to what they called "a pittance"? On behalf of friendly

societies their national conference would receive a deputation of doctors who would be reasonable and not demand a wage limit. Dr. Smith Whitaker said no amicable adjustment could be arrived at without a wage limit. The confession of the club representative that the members of his order would avail themselves of the Poor Law or the free hospital unless they could get the doctor at 2s for a week's attendance speaks volumes for the boasted independence of the working man.

On Tuesday there was a meeting in the College of Physicians in support of the British Medical Benevolent Fund, which was founded in 1836, and has spent over £70,000 in grants and a little over that amount in annuities to distressed members of the profession, their widows and orphans. Legacies and large contributions are invested for the annuity branch, but grants are limited to the annual subscriptions, and the increasing need for these is a source of anxiety to the managers. Last year £1,877 was spent in that way in sums varying from £5 to £20. The amoritants now number 124. A special fund is being started in the hope of raising all annuities to £26 a year. No publicity is given to the cases, and the working expenses are only about 5 per cent. Most of the money is given by the profession—very little being subscribed by the public.

The Bishop of Oxford attended the meeting, and said his father was for many years, and until his death, president of the fund. A glance at the work done would quicken any one's interest in it. No profession run such risks, and when a doctor's education ended he had mostly spent his capital and had much to do to keep up appearances. The dangers to his health were great, but a breakdown might be ruin.

The Lord Mayor and Sir Douglas Powell also spoke in support of the fund.

Dr. Leonard Hill, lecturer on physiology at the London Hospital College, gave a demonstration at the London Institution on the use of oxygen in athletics. He said that athletes used up their oxygen faster than inhaling air could supply it. The beat of the heart and pulse was reduced and the blood pressure raised after inhaling oxygen. He had induced two runners to experiment, and they overran their own records after taking oxygen. He thought taking the gas before an athletic event would lead to record breaking. All athletes are exhausting their hearts by using up oxygen faster than they can replace it and their hearts are damaged for want of it. If they took oxygen before, during and after the game the heart, he said, would be restored and they would not suffer the ill-effects of their exertions.

In connection with this statement it is noteworthy that recently a warning was sent to the head masters of all schools to the effect that school and cross-country races exceeding one mile in distance are wholly unsuitable for boys under 19 years of age, as the strain involved is apt to cause permanent injury to the heart and other organs. This warning is signed by several leading physicians, and is issued by Mr. Farnier, captain of Middlesex football club, etc., from 1886 to 1891.

The Prince of Wales having consented to become an honorary Fellow of the Royal College of Physicians, was yesterday formally elected by the Council. His Royal Highness intends to be present at the Hunterian ovation on Monday next.

Progress of Medical Science.

Boston Medical and Surgical Journal, February 18, 1909.

Criminal Abortion.—The paper of G. S. Taft, a District Attorney of Massachusetts, discusses this matter from the medicolegal standpoint suggested by the laws of that State, and traces the development of the statute enactments up to the present time. The crime is even defined as follows: "Whoever with intent to procure the miscarriage of a woman, unlawfully administers to her, or advises or prescribes for her or causes any poison, drug, medicine or other noxious thing to be taken by her, or with the like intent uses any unlawful instrument or other means whatever or with like intent aids or assists therein, shall, if she dies in consequence thereof, be punished by imprisonment in the State Prison for not less than five nor more than twenty years; and, if she does not die in consequence thereof, by imprisonment in the State Prison for not more than seven years and by a fine of not more than $2,000.00." In Massachusetts it is not a crime for a woman to commit an abortion upon herself, nor to submit to one by another. In the same State, the confidential disclosures made to a physician are not privileged; that is: the physician may be compelled to testify to them in court. In about half the States the law is otherwise, though in such States it is the privilege of the patient and not of the physician, and the patient may waive the privilege.

Fibroid Phthisis in Childhood.—A case of this form of phthisis in a boy of four years is recorded by A. W. Fairbanks. The case has been followed by the author for a period of six years, the boy now being ten. The condition apparently dates back to a pneumonia at the second year, following which the boy had a constant cough. A man in the same house died from pulmonary tuberculosis a year after the child had pneumonia. The physical signs at the different periods are given in full. When the boy was six, he went through a severe attack of bronchopneumonia with consolidation of the entire left upper lobe and bacilli appeared in the sputum. The eventual prognosis in the case it is impossible to forecast. During the last three years the boy had liver on a houseboat in Boston Harbor each season from May through October, and has thus been exposed to the fresh air day and night, not coming ashore at all. He has had no cough, has improved materially and the physical signs are not as pronounced as they were three years ago. This long duration of the lung process, the intercurrent bronchopneumonia with bacilli and the upper left lobe consolidation, disappearance of the bacilli and consolidation, and the present health of the child, although the fibroid process has caused a marked chest deformity, make the case one of much interest.

New York Medical Journal, February 20, 1909.

The Genitourinary Complications of Typhoid Fever.—E. J. Beardsley enumerates these as retention of urine, polyuria, albuminuria, pyuria, hematuria, hemaglobinuria, urobilinuria, bacilluria, infarcts and abscess of the kidney, nephritis, pyelitis, cystitis, epididymitis and orchitis, ovaritis and salpingitis, gangrene of the genitals, disturbed menstrual function, abortion, miscarriage or premature labor and inflammation of the breasts. Some of these are of slight import, giving but little trouble, while others are so severe as to prove fatal after the febrile stage is finished. Albuminuria is very common. Of this the author makes five clinical varieties, viz., febrile, due to nephritis (hemorrhagic); nephritis with acute suppuration, post febrile and due to cystitis. Bacilluria is so common a complication of typhoid fever that we must consider it present in every case at some time during the disease, although the bacillus has been found in but twenty-five per cent. of the patients whose urines were examined. Nephritis in typhoid fever patients is a very important complication. The exact relation of the primary disease to the inflammation of the kidney, which in varying degrees of severity occurs so commonly during its course, is a very difficult question to decide. We know that fifty per cent. of the patients who suffer from typhoid fever reveal both albumin and casts if the urine is carefully examined through the course of the illness, but we also know that a large percentage of these patients recover without untoward effects. In the usual case the albumin and casts appear at the height of the fever, but there are patients who, from the onset of the illness, show marked changes in the urine and reveal symptoms which, for a time, conceal the true nature of the illness. The relation of the pregnant condition to a typhoid fever attack is of much importance. Some patients pass safely through the attack of fever without interruption of the pregnancy, while others recover, in spite of abortion or premature labor. In still other cases death takes place immediately after the interruption of the pregnancy. Regarding the danger of an attack of typhoid fever to a pregnant patient, we may quote the collected statistics of Sacquin, who found that in 223 cases of pregnancy complicated by this disease, abortion or premature labor took place in 150, with a mortality rate of sixteen per cent. Slight inflammation of the breasts during typhoid fever is often seen but the symptom is usually transitory in character. Occasionally, however, the inflammation is more severe and abscesses sometimes form in the pus of which the *Bacillus typhosus* has several times been found.

Salivary Calculi.—R. E. Davison precedes a general article on salivary calculi, with the account of a personal case, his patient being a man of forty-one years with sore throat and swelling about the left angle of the lower jaw, causing difficulty in chewing and swallowing. The trouble seemed to be an enlarged submaxillary gland, there being almost a tide-like regularity in its rise and fall of the tumor with activity and rest of the salivary apparatus, suggestive of a partial obstruction in Wharton's duct. No

probe could be inserted. There was a purulent discharge in the mouth. The following operation was performed: An incision one inch in length was made parallel to the ramus of the jaw and one-fourth of an inch below, and directly over the tumor. By blunt dissection the submaxillary salivary gland and two enlarged lymphatic glands were removed. The salivary gland was free of stone and apparently healthy. The jaw bone was not diseased. These findings led to a diagnosis of a salivary calculus surrounded by suppurating tissue. The stone lay so far back and so deeply in the floor of the mouth that it could not be felt through the incision, consequently, it was decided to remove it through the mouth rather than risk the danger of infection by enlarging the incision. Accordingly the sinus was enlarged by incisions down to the stone, and the calculus grasped by forceps and removed. It was a large stone weighing dry sixty-four grains and measuring three-fourths of an inch long, three-fourths of an inch wide, and a half inch thick. The skin incision was partially closed with silkworm gut and a wick of iodoform gauze inserted for drainage. Healing was uneventful. The author found 242 cases of salivary calculi on record. The treatment of the condition is always surgical. It may be possible at times to leave the gland, but we are never certain that the gland is not diseased, and this is especially true of the submaxillary. In case there is much purulent discharge coming from the floor of the mouth it is better to remove the affected gland. In regard to the parotid gland no general statement can be made, since each case will have to be decided according to the condition present.

Amyluria: Starch in the Urine.—I. S. Wile makes a preliminary communication on this subject, reviewing its literature. In thirty-five children seen at one of the New York City children's hospitals, amyluria has been noted thirty-five times. Various precautions were taken to exclude contamination and ensure favorable conditions for fair observations: (1) Urine from males only was used; (2) lycopodium was used as a dusting powder; (3) penis washed with a flow of water before securing specimen; (4) penis inserted into a clean bottle and held in place through the use of adhesive straps; (5) bottles were covered immediately after the urine was secured; (6) the writer was kept in ignorance of the foods used until after his observations were completed; (7) all centrifuge tubes, test tubes, glass slides, etc., were tested for starch before utilizing them for the work. The author's results as thus far collated are expressed in the following propositions: (1) Starch granules are absent in the urine of breast-fed infants; (2) starch granules are frequently present in the urine of infants on carbohydrate food; (3) the degree of amyluria varies with the nature and preparation of the food, the quantity ingested, and the condition of the individual; (4) starch in urine at times gives a reaction simulating that of albumin; (5) starch passing through the kidneys may cause albuminuria with casts; (6) amyluria does exist, and starch in the urine is not necessarily of extraneous origin. In one case starch granules have been found in the blood (amylemia). The difficulty of determining amylemia are obvious. Further investigations are under way.

Asthma: A Nasal Disease.—J. H. Egbert gives the histories of a group of eight cases of asthma in which great relief was experienced upon the correction of abnormal intranasal conditions. The paper is a very good exposition of one side of the asthma question. The author admits the existence of two additional causative factors: (1) A neurotic habit, and (2) acquired nonresistance. He says that the remedies most commonly employed to relieve asthma are enervating depressants, while not a few of the agents employed by inhalation are directly irritating to the nasal mucous membrane or otherwise determine a loss of nerve and tissue tone. Lobelia, stramonium, tobacco, and allied agents which are capable of allaying the paroxysms of asthma, do so by depressing the pulmonary nerve supply to the verge of narcotism, thus often effecting more injury than benefit by occasioning general systemic derangement and by further debilitating an already atonic nerve organization. The nitrites are open to similar objections for, while these agents do not produce the same profound central narcotism, they exert a similar paralyzing influence on the peripheral nerve supply of the lungs and so long as this is maintained asthmatic paroxysms may be held in control. Pilocarpine is supposed to act somewhat similarly to the nitrites, though this drug has, perhaps, a more logical application in that it reduces visceral blood pressure by occasioning dilatation of the peripheral capillaries. Its use, however, is not without danger, and nausea, extreme depression, and collapse may follow its exhibition in regular therapeutic doses. The medicinal agents which will be found to be most generally useful in the treatment of asthma are strychnine, atropine, phosphorus, and quinine—all nerve invigorators. The nose must be put right. All concurrent functional and organic disorders must be put right, cardiac, renal, or hepatic. Bad habits must be given up. A warm, dry climate is beneficial.

Journal of the American Medical Association, February 20, 1909.

Dropped Heart Beat.—D. Felberbaum and L. J. Pollock have studied the relations of so-called dropped beat and hemisystole, the latter being a condition allied to cardiabigeminus in which during the second beat of the heart the left ventricle fails to contract. It has been observed in the exposed hearts of animals but most authors deny its occurrence in man except in the dying, what really occurs being a partial or ineffectual contraction of the ventricle, producing a pseudohemisystole. Two cases are reported and the authors deduce the following conclusions: "(1) From our observations in numerous cases of cardiac arrhythmia, dropped or missed beats occurring from time to time are not rare. Such exquisite types as we have illustrated are, however, exceptional; (2) a condition demonstrating the mechanism of pseudohemisystole is observed in irregularly acting hearts during the periods of consecutively dropped beats; (3) a regularly consecutive dropped beat constitutes pseudohemisystole; (4) that this condition is not due to disturbances of conductivity is shown by the response of the ventricle to the action of atropin; (5) the absence of a second sound to the second beat, so well shown by case 2, is due naturally to the nonclosure of the unopened aortic valves; (6) the absence of a murmur during the period of dropped beat in case 1 further demonstrates an ineffectual ventricular contraction, since the force exerted was insufficient even to cause a regurgitation of blood into the auricle and produce a murmur."

Obstruction of the Bowel.—J. S. Horsley calls attention to two points in the treatment of mechanical and dynamic obstruction of the bowel. The first of these is the abuse of purgatives in this condition. There are few things calling for more judgment and skill than the correct and timely use of purgatives. In acute infections and in any case in which a toxemia may develop, a purgative is not only advisable but necessary, but it is different with acute obstruction from any other cause. A sudden obstruction, not due to nervous affections, always means one of two things: either an inflammatory condition of the peritoneum or else some form of mechanical obstruction. When an inflammatory condition is present purgatives are contraindicated unless the toxemia is so excessive that the constitutional improvement by the elimination of the toxins by the purgative outweighs the local damage produced. In inflammatory conditions rest is needed for the part, and we should endeavor to inhibit peristalsis rather than to increase it. When the acute obstruction is due to some mechanical cause, the contraindications are even plainer. The more vigorous the purgative the more absolute the obstruction and the greater the distention above it. The other point noticed is the surgical method of relieving the obstruction, and the earlier this is resorted to after reasonable efforts have been made to produce evacuation by enemas, etc., the better for the patient. When distention is very marked an enterostomy may be needed to drain the bowel and carry off the toxins. When resection is attempted the method is of great importance. Horsley objects to the use of a fixed metallic body, with a small lumen, like the Murphy button, which by its weight may cause kinking or volvulus, considering carefully placed intestinal suturing by a skilled hand much safer and hardly less expeditious. When the bowel cannot be brought out into the wound and sutures accurately placed, the button may be indicated, but such cases must be rare

The Surgery of Syphilis.—G. F. Lydston emphasizes the fact that many practitioners treat syphilis too specifically and that in many cases radical surgical measures are the primary indication, specific medication taking almost a secondary position. The initial lesion rarely requires the knife, save in case the duration is very persistent and defies specific treatment for a long period. Here a clean excision is sometimes of great advantage, and the more thoroughly the patient has been previously treated with mercurials, the less the chance of a recurrence. The most frequent call for surgery in primary syphilis is in hidden chancre or mixed sore with phimosis. He has long since given up all hesitation in such cases, the chances of wound

infection being almost negligible as compared with those of allowing the lesion to progress without diagnosis or proper treatment. In his own experience he has never had occasion to regret making a dorsal incision of the prepuce for the purpose of freeing the glands and inspecting and treating the concealed lesion. Marked edema occurring with chancre sometimes demands multiple punctures, and this is preferable in persistent cases to permitting the edema to be followed by connective tissue hyperplasia calling for the knife later. In mixed sores and superadded pus infections in true chancre, abscesses may occur in the course of the lymphatics of the penis, which, of course, call for incision. It is hardly necessary to say that the syphilitic bubo, *per se*, needs no surgery, but when there is chancroidal or tuberculous infection the knife is called for. Lydston here pleads for thorough extirpation of the glands in such cases; halfway measures are not effective, according to his experience. The surgery of secondary syphilis is still more limited. Induration after edema may call for it and obstinate mucous patches and ulcers may do well under light curettement. Various conditions of the jaws and teeth have an important relation to these lesions and call for surgical treatment. It is in late uncured syphilis that surgery becomes of more and more importance in the treatment. The same indurating edema noticed above is often encountered in broken-down subjects of tertiary syphilis. Extensive tumors about the genitals may thus result and may persist long after the luetic infection is under control, and should be dealt with just as any other new growth would be. The mistake is often made of trying to cause their disappearance by specific treatment; they are no longer syphilitic, but are merely the results of syphilis. Gumma in certain situations should be treated surgically more frequently than is the custom. Lydston holds that obstinate gumma of the brain, resisting internal medication, and when accurate localization is possible, is one of these conditions. The same is true of stubborn gummy ulcers which are likely to heal after the indurated base is cut away, always provided that the constitutional treatment has been judiciously carried out. Syphilitic bone disease is the cause of more barbarous specific overdosing than any other lesion occurring in syphilis, and many cases of caries and necrosis are the result. Mercury and iodid, must, of course, be the mainstay in the constitutional treatment, but the local condition must be treated on its merits as if it were due to other causes than syphilis. Lastly Lydston calls attention to the frequency with which gummata and obstinate ulcers of the tongue are replaced by malignant disease. In such cases the diagnosis is often delayed and the patient continues to be dosed with iodid and mercury to his damage. Lydston has observed a large number of such cases in which the opportunity for the cure of the disease by surgery has been lost. He thinks that the profession as a whole, is woefully unobserving in this class of cases. He has, he says, arrived at the point where, when the microscope is guessing, he is perfectly willing to hazard his reputation by playing the only surgical trump at his command and removing the tongue. Operations on syphilitic patients, he says, in whom the constitutional disease is under fair control by specific medication, are likely to result in primary union of the wound just as though syphilis did not exist. In clean aseptic incised wounds repair will occur quite as rapidly as in nonsyphilitic subjects. In open wounds, or in chronic nonspecific lesions occurring in syphilitics, where irritation is marked and persistent, the syphilitic constitution undoubtedly delays repair, and the rational use of mercury and iodids is an indispensable adjuvant.

An Epidemic of Acute Anterior Poliomyelitis.—R. Minor Wiley and J. C. Darden report an epidemic of infantile paralysis occurring last summer in Salem, Va., and vicinity. There were twenty-five cases altogether, while a neighboring city of 35,000 inhabitants escaped with only one case though only seven miles distant and daily visited by scores of Salem people over a connecting trolley line. Inquiries made by the State Commissioner of Health developed no other cases in the State, and the condition was without precedent in that section of Virginia. The cases are reported. They were in children under five years of age except in one case, a boy of six. The youngest patient was thirteen months old. There were seven cases involving only one leg, one in which one arm only was affected; five cases in which one arm and one leg were paralyzed, one in which one arm and the leg of the opposite side were affected, six cases in which both legs were involved, four in which all the limbs were paralyzed, five cases with bulbar paralysis, and three deaths, or a mortality of 12 per cent., which is higher than usually reported. In all the fatal cases there were respiratory and cardiac paralyses. A striking feature noted in the majority was pronounced hyperesthesia, and another was profuse sweating. The fact that not more than one case occurred in any house, though other children were exposed, would speak against the contagiousness of the disease. The epidemic was preceded by intense heat and humidity and there were no new cases occurring for three weeks during which there was a drop in the temperature, though they began to appear again when hot weather recurred, thus pointing to an influence of the weather upon the disease. Eight patients recovered completely and fourteen partially, but all the latter have since shown some improvement and some may ultimately recover. The authors cannot give details of treatment except in their own cases. They employed counterirritation and salicylates in the acute stage, followed later by increasing doses of potassium iodide and strychnine to the point of toleration, together with massage, warm baths, and electricity when practicable.

The Lancet, February 13, 1909.

An Inquiry Concerning the Etiology of Beriberi.—This paper results from the studies of H. Fraser and A. T. Stanton, who give the following facts: Twenty cases of beriberi occurred among 220 people fed on white rice. No case occurred among 273 people fed on parboiled rice and otherwise under precisely similar conditions to the first group. Various doubtful cases of the disease occurred, but these were all excluded. All of them had eaten white rice, not parboiled. No case occurred among the white rice eaters unless they had been on this diet for at least 87 days. No special organisms were found in the blood and urine, except those well-known as causative factors of other diseases. The author's observations convince them that the disease is not a directly communicable one. Removal of the patients from one place to another had no effect on the disease so long as the patients continued on the white rice diet. The authors cannot regard as proven the assumption that a given place may become a nidus for the disease. The substitution of parboiled for white rice led, in three instances, to a cessation of the disease. There was no evidence to show that any other article of food outside of rice entered into the matter of causation of the malady. No more intestinal worms were found in the beri-beri cases than were found in the well population in the same locality (Malay States).

An Unusual (? Instructive) Case of Appendicitis.—The patient of F. C. Smith was a young physician who entered hospital after an illness of five days, his most prominent symptoms being abdominal colic and diarrhea with fever. On admission a tentative diagnosis of typhoid fever was made and the abdomen carefully examined for a possible appendix inflammation, but none could be discovered. Later, deep palpation revealed some tenderness in the region of the gall-bladder and some change in the other symptoms led the author to a diagnosis of pylephlebitis from some form of ptomaine or food poisoning. He lived for nearly two weeks. Blood tests were negative. He had several rigors during the time, but in spite of various abdominal examinations no justification for surgical measures could be found. For the last forty hours of life he had manifestly acute general purulent peritonitis. Autopsy showed a gangrenous appendix and in the liver three large distinct abscesses the size of golf balls, with greenish slimy contents, not pus, and a pathological antemorten clot in one of the larger branches of the portal vein. In view of the autopsy findings the author says the case shows a logical sequence in the development of pathological processes, but he cannot understand why the abdomen failed to show any of the signs which we are accustomed to consider as of regular appearance in appendix cases.

The Etiology of Psoriatic and Allied Conditions.—M. J. Chevers believes in the neuropathic theory of the origin of psoriasis. It results from a denutrition and structural destruction of the epidermis, an exfoliation of the epidermis and dried leucocytes, brought about by a drying and shriveling up of the epidermis, for want of its necessary nutriment which it obtains by inhibition from the derma. This blood hunger is a local manifestation of a general systemic condition which shows itself by a giving way at its weakest point, viz., the very fine cutaneous trophic nerves and interference with the fine capillary circulation in the derma, loss of tone in these capillaries allowing of their compression by the abundant elastic fibers of the corium and the unstriped muscular fibers of its superficial layer. All these changes produce an interrupted blood supply to the derma and serous exudation

beneath the epidermis. In individuals whose epidermis resists rupture long enough to allow of a drying up of this exudation, we get exfoliated epidermis plus dried leucocytes, in other words, the psoriatic condition. The occurrence of the disease on the dorsal surfaces and on the thickest of these as the elbow and knee is explained by the fact that the thicker the epidermis, the less the number of nerve fibers as is evidenced by the reduced sensation in these areas and the consequent greater ease of disturbing the life and function of the epidermis by lessening its power of securing nourishment from the corium, the blood supply to the latter being curtailed by the general atonicity of the nervous system. The individual variation in permeability of capillary walls, coagulability of the blood and elastic contents of the skin explain why, from the same general causes, there may be in one patient, dry, scaly conditions as psorasis and in other patients such conditions as most exudative psoriasis, eczema and pemphigus. The laxness of the flexor and more tense extensor aspects of ceratin areas determine to some extent the location of the dermatosis.

The Anatomical Varieties and Their Bearing on the Treatment of Pathological Varieties of the Palatine Tonsils.—In an illustrated paper G. S. Heit describes the origin and development of the faucial tonsil, of which he recognizes the following clinical types: (1) Imbedded, (2) projecting, (3) flat, (4) hanging, (5) with marked preponderance of one or more of the constituent masses, and (6) with marked lingual prolongation. The author says that the size of a tonsil is no criterion for the necessity of surgical intervention. Sepsis, not size, is the determining factor. The fact that the tonsil does not project beyond the faucial pillars is no proof that there may not be a deep imbedded mass. Before any tonsillotome is used, the tonsil should be thoroughly separated from the pillars. The remains of tonsillar tissue may be bound down by fibrous bands and so form a nucleus for infection. Many cases of recurrent sore throat are due to this cause. We recommend this paper to those laryngeal zealots who operate on every tonsil large enough to be seen with the naked eye.

British Medical Journal, February 13, 1909

Can Opsonic Estimates Be Relied on in Practice?—E. C. Hart says that the work of the Wright school must be reckoned with in clinical medicine, but that it is doubtful whether opsonins represent more than a fractional part in the highly complex machinery of immunity production. Granted that they are the important factor in immunization, the question as to their reliability is still open. Technical considerations of standardization of emulsions, cultural difficulties, agglutination questions, etc., concern only those experts whose responsibility it is to render such technicalities as free from sources of error as possible. They do not affect the practising physician, whose only concern is with the pertinent questions of reliability and cost. As regards cost, everyone knows that it is necessarily high. As to reliability, countless observations have been reported in which the estimations have appeared to be of the highest value in diagnosis and determining treatment. But such experience is not universal even when securing the best talent among the exponents of the opsonin theories. There appears to be a growing conviction, says the author, that except possibly in the hands of an extremely small band of experts, the method is not of the general utility with which it has been credited.

Iodine in Surgical Tuberculous Disease.—W. A. Tatchell, who is a mission surgeon in China, commends the use of iodine in tuberculous ulcers, abscesses, glands, etc. He operates and scrapes as usual. Then the cavity is thoroughly swabbed with iodine liniment, which is applied daily. The application causes but little stinging pain and it does not destroy tissue as does carbolic acid. Granulations do not become excessive. At the first application thin gauze or light packing are used, but not later. Drainage gauze and strips have doubtless caused many sinuses. Internally, syrup of the iodide of iron and small doses of potassium iodide are given thrice daily

The Nature and Treatment of Parenchymatous Goiter.—According to Francis L. A. Greaves, there is in this affection glandular proliferation which results in clusters of cells or of gland like acini lined with epithelium, somewhat flattened and irregular as compared with the normal gland. Both varieties may be seen in the same organ. The cut surface of a fresh goiter appears reddish or dark brown. Areas in which many of the acini contain masses of colloid material show on section a translucent, honey-like appearance. The symptoms and course of the malady are given in full, nothing new being presented, and a technical description of the operation for removal is given in full. The author has operated on nearly forty patients and all have healed without incident except one in whom suppuration occurred.

The Signs of Early Disease of the Thyroid Gland.—G. R. Murray divides the cases into two classes. In one the gland increases in size and the symptoms are mechanical, due to pressure on surrounding organs. The other symptoms are referable to variations in the functional activity of the gland induced by the structural changes occurring in it. As the function of the gland is to supply an internal secretion, which escapes by way of the lymphatics into the blood stream, thyroid diseases may be divided into three classes, according to the manner in which this function of the gland is influenced by them. Some diseases have no effect on the secretory function, as acute thyroiditis, simple parenchymatous goiter, and many cases of a denomatous or cystic goiter. Some diseases lower or abolish it, according to their severity, as cretinism or myxedema, while in a third class, as exophthalmic goiter, the function is greatly increased and possibly perverted. Pregnancy and menstruation produce a temporary enlargement. In many persons the gland enlarges permanently, with a possible visible enlargement of the veins and absence of thrill or murmur. As a rule, when a goiter is unilateral the enlargement is due to an adenoma or cyst in one lobe. Myxedema cases generally come on during the fifth decade of life and are more common in women. The change is accomplished by the characteristic mental alterations, and a subcutaneous swelling of the body. The skin becomes dry and desquamates, especially on the legs. The hands become pudgy on the back. The cheeks often enlarge and a flush appears, suggesting an unusual condition of health. If at the time of the appearance of these symptoms the ovary atrophies, we have the usual accompaniments of the menopause. If we have hypersecretion of the glands, we have the usual goiter, exophthalmus, rapid heart nervousness, tremors of the hands, and emaciation. We are not to place too much dependence on the presence of the exophthalmos, as it is absent in one-quarter of all cases. The reason for this is unknown. In its absence a staring expression may be noted, due to a spasm of the levator of the upper lid. It is well to remember also that if a patient has been taking for any reason large doses of thyroid for a long time a condition of thyroidism may arise in which many of the symptoms of Graves's disease develop, such as rapid heart tremor, nervousness, sweating, and emaciation.

Dysentery and Its Serum Treatment.—P. Aubrey advocates the use of antidysenteric serum in bacillary dysentery which is sometimes epidemic in a severe form in temperate climates. It has been tried sufficiently in animals and in human beings to show its value. It shortens the attack, lessens the mortality from the disease, and lessens the pain that the disease occasions. The pain is decreased, the fever and general symptoms are improved, and the stools lessen in number and change in character for the better in a few hours. Attacks of moderate severity may be cured in two days, while severe ones end in five or six days. The dose is from 20 to 100 cubic centimeters. If used in ten cubic centimeter doses as a prophylactic measure, an immunity of ten days may be secured in time of epidemic.—*Revue Française de Médecine et de Chirurgie.*

Observation of the Hematology in a Case of Hemophilia.—F. Costantini describes the examination of the blood of a patient treated for hemophilia because the blood observations of such cases are somewhat rare and contradictory. In some respects the results of this examination differed from that ordinarily obtained. The patient was suffering from a hemorrhage of the lower lip which recurred without cause. Her father and four brothers had been subject to hemophilia. The time of coagulation was normal or a little hastened. Hemoglobin was diminished. The red blood corpuscles were increased in numbers. The globular value was low. The number of white blood cells was somewhat increased but not beyond normal limits. The leucocyte formula showed a diminution of polynuclear neutrophiles and an increase of the lymphocytes. Mast cells were increased in number.—*Gazzetta Medica di Roma.*

Book Reviews.

Gonorrhea in Women. By Palmer Findley, M.D., Professor of Gynecology in the College of Medicine of the University of Nebraska, Omaha; Gynecologist to the Clarkson Memorial Hospital and Wise Memorial Hospital; Fellow of the American Gynecological Society. St. Louis: C. V. Mosby Medical Book and Publishing Co., 1908.

This monograph of 112 large octavo, highly calendered pages, is certainly a masterpiece of careless writing, shiftless proofreading, and reckless disregard of the reader who seeks information. The author doubtless knows his subject, but through the facts above related most successfully obscures his meaning in the majority of instances. Painful surprise is created by the author's most original presentation of Latin letters which somewhat resemble those of the Greek alphabet. Thus we are told that the average diameter (of the gonococcus) from pole to pole is 1.25 *u*, and that Galen attributed the name gonorrhea to *youn*, seed, and *pew*, to run. Perhaps, however, this literary curiosity is to be credited to the printer's economy, preventing the acquisition of a Greek font. Rare is the page of this book, in which at least one sentence or one paragraph is not a marvel of obscurantism. While the author certainly must have known the meaning he desired to convey, his phrases are so involved as to defy even the hardened reviewer. It must be conceded, however, that perhaps one-quarter of the book is not at all subject to the preceding strictures (urethral strictures are not mentioned in the book). The pages alluded to are mainly from the writings of Bumm, Leedham-Green, who here is disguised as Seedhal-Green; Saenger, Taussig, Taber-Johnson, Morrow, Cushing, Boldt (who would hardly recognize himself as H. I. Bolt); Bierhoff, Grandin, George Tucker Harrison, Osler, and other masters of their craft and of the pen. The extensive citations from their contributions to scientific literature do not always appear relevant to the subject in hand. From some of the literary references we learn that Keifer's "Beitrag zur Festschrift, gewidmet A. Martin" has "schöne Abbilduggen der Kulturen"; that Mayer's "Gonorrhoea und Wochenbett" presents "ausführliche Literatur uben diesen Gegenstand"; that Ccckas in a paper Zur Behandlung der Blennorhoe, "empfiehlt heisse Spulungen den Harnrohre" (*copia verbat. et literat.*). Bontin will doubtless be astonished to learn that he write his Thèse on la Blonnattagie, as will some of our American colleagues, who do not understand German, to be informed that Cahen-Brach's Urogenitalblennorrhoe contains "eingehende Literatur-angaben." It is not at all impossible that this book is the work of a competent practitioner, who can teach *viva voce*, but whose literary productions need the aid of a skilled pen.

Diseases and Surgery of the Genitourinary System. By Francis S. Watson, M.D., Senior Visiting Surgeon to the Boston City Hospital; Lecturer on Genitourinary Surgery, Harvard Medical School; Member of the American Surgical Association, of the American Association of Genitourinary Surgeons, of the American Urological Association, of the International Association of Urology and its first Vice-President; Corresponding Member of the Surgical Society of Moscow; assisted by John H. Cunningham, Jr., M.D., Visiting Surgeon to the Long Island Hospital, Boston; Assistant Visiting Surgeon to the Boston City Hospital; Member of the American Urological Association. Vol. I. The External Genitals, the Prostate and Bladder, with 339 Engravings and 23 colored plates; Vol. II. The Kidneys and Ureters, with 115 engravings and 24 colored plates. Philadelphia and New York: Lea & Febiger, 1908.

Had this magnificent work been published in one volume, the present general index for both would have sufficed, and the consequent elimination of individual indices would have reduced the work to a volume of 1099 pages, rendering it quite a conveniently-sized book, more especially if lighter but equally strong paper had been employed. The price of the work would then have been within the reach of the majority, who need just such instruction as the work contains. The book is devoted essentially to surgical anatomy, pathology, and operative technique. In all these regards it is as complete as modern urogenital surgery demands. The tone is essentially majesterial, supplemented by critical references to the works of other authors. As is natural, in a study devoted to surgery, acute urethritis receives but curt attention in 29 pages, and urethroscopy is disposed of in 18 pages. In the latter a colored plate of endoscopic pictures is very poor, more especially when compared with the other most excellent illustrations in which the work abounds and which ably supplement the terse, clear text that, although elegant, is never redundant. In the treatment of gonorrhea, the author declares himself on the side of those who do not favor irrigations, believing that "with its employment there is always the danger of carrying infection to the posterior urethra * * *" (p. 64). It is remarkable that in so excellent a work as this, no case of infection to the posterior urethra is cited in support of the assertion. The danger meantime, in view of the thousands of irrigations performed daily for the past fifteen years or more, seems purely theoretical. No such exception can be taken to the other, purely operative parts of the work, whose substance, presentation, completeness, and instructiveness defy reviewing. Barely a conception of the immense surgical value of the work can be given in so brief a notice as the necessary space limitations permit. The work certainly will find a place among the books valued by all those whose efforts are directed to genitourinary operations. When other authorities differ, as for instance, in the several prostatectomies, Watson describes each one in detail and aids, especially younger operators, in the selection of the procedure best calculated for the case in hand. Based as the work is on scientific principles, it lays down rules that are the outcome of experience and as such enriches the profession more than has any other book published in the English language in several years.

Die Sprache des Kindes und ihre Störungen. Von Dr. Paul Maas, Spezialarzt in Aacher für Ohren, Nasen und Halsleiden, und Sprachstörungen. Mit 16 Abbildungen. Würzburg: Curt Kabitzsch (A. Stuber's Verlag), 1909.

This little monograph considers the development of the function of speech in the human being and the disturbances of this function met with in children. Treatment of such disturbances, especially of stammering, receives a good deal of attention in the booklet. The work is written in a very entertaining manner, and will repay the time spent in its perusal to anyone interested in the development of the faculty of speech.

A Reference Handbook for Nurses. By Amanda K. Beck, Graduate of the Illinois Training School for Nurses. Second Edition, Revised. Philadelphia and London: W. B. Saunders Company, 1908.

In this second edition there is some new matter, such as domestic and foreign postal rates, and additions to the section on weights and measures, both of which are unimportant, but are probably accurate. There is also a new section on toothache and its emergency treatment. If this latter is a sample of what nurses think themselves called upon to do, we can only say that we prefer the toothache to the treatment here recommended. The dose of dilute hydrocyanic acid is given as one to five minims; so, again, we would prefer to be treated by a physician, and live, rather than to be treated by a nurse and die. For tables of weights and measures and postal rates and similar matters the book can be commended to nurses and others.

Analytique de l'Esprit Humain et de la Vie (Bio-Animisme), du Dr. J. A. Molinié, Ancien Interne de l'Hôpital International. Paris: Vigot Frères, 1907.

This is a brief study in analytics exploiting a doctrine of biological philosophy; an effort to elaborate the old socratic formula, know thou thyself, on the basis of anatomico-physiological discoveries; in other words, to unite the old scholasticism with modern scientific progress. Among the more interesting chapters are those on the center of ideation, on character, and on vitalism, or, as the author terms it, bio-animisme.

Zeittafeln zur Geschichte der Medizin. Von Prof. Dr. J. L. Pagel. Berlin: August Hirschwald, 1908.

This is a collection of chronological tables by means of which one can at a glance inform himself of the main points of medical history at any particular period or in relation to any particular investigator, and also the main facts of general history for the same period. The three periods into which the author divides medical history are those of antiquity, extending from the earliest time to the end of the classical period of Greek and Roman history; of the middle ages, from the fourth to the fifteenth centuries; and of modern times, from the beginning of the sixteenth century to the present. The tables are well arranged and self-explanatory, and exceedingly useful, but their value as a work of reference would have been enhanced tenfold by an index, at least of names, which is most provokingly absent. The brief table of contents in no way supplies this deficiency, though it is helpful as pointing to specific periods with which the tables deal.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held January 18, 1909.

Dr. H. Seymour Houghton in the Chair.

Address of the Retiring President.—Dr. J. Riddle Goffe, in welcoming the President-Elect, assured him that with whatever feeling he had assumed the office he would relinquish it with a far livelier sense of its dignity, its responsibility, and its honor. He said that he had been profoundly impressed with the conscientious work done by the Comitia Minora, the Board of Censors, and the Milk Commission. Previous to his entrance upon official work he had had no conception of the time required of the members of these executive committees and of the promptness, interest, and thoughtful judgment that each and every man devoted to his duties. These methods and traditions could be handed down from year to year only by the system of organization which carried over the membership of a sufficient number of the older members to leaven properly the new organization. This was especially true of the Board of Censors, where questions of the most delicate nature were constantly arising. The machinery of the Society had run with the greatest possible harmony during the past year. The proceedings of the Board of Censors, in so far as his observation went, had been carried on with the most perfect impartiality in dealing with members of the Society for minor breaches of medical etiquette and those of a grosser nature had been met with unflinching courage and diplomatic tact. Dr. Goffe suggested that the make-up of the Board of Censors should be guarded with the greatest care. As the family was the unit and foundation of all civilized society throughout the world, so the County Society was the unit upon which the superstructure of medical organization rested. While the County Society existed primarily for the dissemination of medical knowledge and experience, these records depended, to a certain extent, upon the personal equation and one could become acquainted with the natural bias of the individual only by a personal intimate acquaintance. The members must know each other. The aim in each county should be to see that every respectable practitioner was a member of the local society and that every practitioner who was not respectable should be turned out of the profession. When it become necessary to know "who's who," and to have means of exchanging ideas and securing a rating of the man in the medical centers and the distant parts of the State, nothing met these requirements so completely as a State Medical Directory and a State Medical Journal. He urged that the delegates to the State Society would stand solidly for these instrumentalities which kept alive and responsive the organization as a whole. He referred to malpractice defense in the organization as working most satisfactorily. He had been informed that Mr. Lewis, the counsel for the Society, had never lost a case, with one exception, in defending members against malpractice prosecutions. He had also discouraged threatened prosecutions so that many had never come to trial, and that without compromise in a single instance. The exceptional case had been carried to a higher court. Dr. Goffe said that he relinquished his office with regret, as he had enjoyed to the fullest extent the confidence, support, and cooperation of the entire Society. He felt sure that the same loyalty would attend the incoming administration. The past year had witnessed a greater accession of new members than any year in the history of the Society, and the monthly attendance had been larger than was shown by any previous record. They had certainly been favored with peace and harmony, and had been afforded opportunity for a more lively pursuit of science, and it was with a feeling of great satisfaction that he relinquished the office.

Inaugural Address.—Dr. H. Seymour Houghton, the incoming President, said that the honor conferred upon him was one which he deeply appreciated. He took up the duties and responsibilities of the office with no sense of victory won, but with not a little faint-heartedness, though glad to contribute his share to the work to the fullest extent of which he was capable. He stated, not because it was new, but because there might be some who did not fully appreciate the fact, that the reorganization of this society established it at once on a plane of equality in prestige and importance with all the societies which made up the organized bodies of medical practitioners in this country. There were many who were not members who did not grasp the importance, both to themselves and to the society, of becoming identified with the organization. Special efforts were now being made to interest properly qualified practitioners in this city to become members. The special Committee on New Members was doing much in this direction, and every member of the Society should do his share of this work. There had been 155 new members added to the list during the past year, a net increase of 48 after the deduction of 26 lost by death, 16 who had resigned, and 65 who ceased to be members because of nonpayment of dues. The object and end of this society were different from those of private societies. In a private society it was desirable that the limitation of the number of members, the elements of congeniality, of similarity in tastes, and of personal friendship should figure, but the object of this Society was one which did not take these features into consideration. It had a duty to perform and a work to carry out in just the proportion which its membership permitted. Each one who came into membership contributed his share towards the efforts to better the conditions of medical practice in this city. Dr. Houghton emphasized the fact that the State Society offered defense to each member in case of suit for malpractice. He wished that the system of protection might be extended to those conditions which fell just short of actual attempted blackmail, but that were equally disastrous to the reputation of the physician. He hoped that concerted action in this matter would be taken at once. Such features were liable to be dangerous ones to the finances of the Society; they were, however, duties which the Society owed to its members. Were it found that a deserving and worthy member was in danger as to his reputation from these causes and was denied the all-powerful aid and protection of our Society because funds were low, he would be loath to believe that those present would refuse an appeal for a dollar or two apiece to protect him, not knowing who might be the next victim. He also spoke of the value of the Directory. It did no harm to repeat what might be a well-known fact, that the authorities of this city would not and did not take the initiative in prosecuting offenses against the medical law, whether these offenses were actually criminal or the practice of medicine without the legal qualifications. These authorities thought that they did their duty when they took up a case and prosecuted it after it had been properly prepared by the Society's counsel. Much of this work was of an unpleasant nature and he was aware that aversion to it and to the methods used was held by some of the members. The soundness of this criticism was recognized, and the Society would be glad if this species of work could be eliminated from its curriculum and given to some organization having for its special object the prosecution of illegal practice. It had been regarded as more consistent with the dignity of the Society to obtain prison sentences for flagrant or repeated offenders rather than money fines. He said that he would take this opportunity to refer to a condition which obtained

in the practice of the criminal element of these people, which he did not believe that one in twenty of those present fully understood; if a physician entered the room of the victim of a criminal operation, and the police became aware of it, even though the physician entered the room not knowing the nature of the case and, finding its nature, refused to have anything to do with it, the police, if advised that he was the last physician who had seen the patient, had a legal right to go to that physician's home and send him to a cell. There was absolutely no protection against this, and he would rejoice to see a change in this system. The magnificent work done, not only to create a clearer understanding of the nature and means of prevention of tuberculosis, but the wonderful progress made in bringing this understanding to the knowledge of the general public, was deserving of commendation, as was also the growing interest in the prevention of ophthalmia neonatorum. The Society was glad to lend its aid as an organized body to those who were doing so much in advancing our knowledge of these matters. In conclusion he said, as for himself and for his fellow members of the Comitia Minora, they had taken the work of the Society to heart, and proposed to continue it to their utmost ability and with fairness to each individual member. He urged such an interest as would make the body a formidable force for good.

Report of the Committee on Ophthalmia Neonatorum.—Dr. John Van Doren Young made this report. He read a letter from Dr. Charles Stedman Bull in which Dr. Bull stated that he had been requested by the Committee on Ophthalmia Neonatorum of the American Medical Association to bring to the notice of the District Branches of the New York State Medical Society, at their next regular meetings, the recommendations of the above committee for the control of ophthalmia neonatorum throughout the State. These recommendations consisted of the suggestions of the State Board of Health for stamping out the disease and the plan of Dr. Wheeler.

Correlation of Physiology and Infant Feeding; Indispensability of Breast Milk; Ability to Nurse; Artificial Feeding.—Dr. Joseph E. Winters said that during the last quarter of a century the mortality among children continued about the same, while the mortality among older persons had decreased nearly one-half; the former he considered to be due to the thwarting of Nature's plans and the lack of dissemination of knowledge of the physiological necessities of growing infants and the meager nutritive value of foods given them. Breast fed children were seldom ill and rarely came under the physician's care. An ample amount of fat of a superior quality in woman's milk should suffer no curtailment. Fat was paramount as a source of heat; to sustain the heat and nervous energy of an infant, fat must be present in large amounts in the milk. There was an expenditure of 130 calories per kilo of body weight in a young infant, whereas in an adult it was 35. That 6 per cent. or more of the fat in a woman's milk was physiological was declared by the fact that there was a certain amount of fat in the brain, and especially by the fact that in the marrow bone there was 96 per cent. of fat. During the first two years of life, the brain doubled in weight. In order to keep up this supply of fat in young infants, it was necessary that a sufficient amount of fat be received. When the mother's milk, or artificial milk, was deficient in fat, there followed a profound innutrition, such as anemia, a pale and worn body, etc., which showed a famished bone-marrow and nerve. On the other hand, when the milk contained an ample amount of fat, the infant was animated, rosy, and joyful. Foods that were deficient in fat were answerable for the little old men and women who never smiled. With regard to fat indigestion, Dr. Winters said that separator cream superinduced this. In separator cream each fat globule was surrounded by protein; this conglomerate fat was as indigestible as cheese. Separator milk of a Jersey or Guernsey cow should never be used in baby feeding. Women's and cow's milk both contained two proteins, albumin and casein; albumin formed two-thirds of the protein of women's milk, and casein four-fifths of the protein of cow's milk. Albumin did not undergo coagulation in tough, leathery masses. An infant's pylorus was so narrow that it only permitted the passage of a small probe; the pylorus was surrounded by a protuberant firm muscular ring. The noncoagulable albumin of a woman's milk made its way through the pylorus into the intestine; but the casein masses of cow's milk could not pass through the pylorus. Every mother who was able to nurse her child should be made to do so. As a rule obstetricians did not lay sufficient stress upon this point. So soon as the mother had received proper attention after the birth of her child, the infant should be placed at the breast; this immediate nursing had saved many children's lives. He cautioned against giving water from a bottle to a newly-born infant; refusal to nurse would follow. Vigorous nursing was wanted in order to stimulate the secretions. Water should not be misused; as long as the baby got water from a bottle or from a spoon, it would not nurse. The child should be left at the breast until satisfied and the head fell away from the breast. Young and inexperienced mothers should not be told of vomiting of curds, green stools, colic, deficient milk supply, etc., because it created great alarm among them. Nursing by clock and scales was an absurdity. The amount of protein in milk diminished with advancing lactation, and after the second month this diminution was especially decided and rapid. During the first two months, the mother and child were indispensable to each other. Up to that time the mother's milk was a perfect food. During the third week of lactation the amount of albumin decreased and casein increased in the milk and the irremediable difference between women's and cow's milk was gradually eliminated. Pasteurized milk was not the proper food for an infant. The rosy, plump, lusty infant was never seen when pasteurized milk was the only food given for a prolonged period of time. Pasteurizing the milk did not render dirty milk clean, nor stale milk fresh. Physiological chemistry positively interdicted the use of pasteurized milk. Dr. Winters closed by asserting the mother's milk was the only proper food for an infant, and that all the foreign and modified milk preparations increased the mortality.

Dr. Barton Cooke Hirst of Philadelphia said there were three special duties of obstetricians for the near future: (1) the prevention of ophthalmia neonatorum, (2) the insistence upon natural nutriment for the new born baby, and (3) a timely recognition and surgical cure of all the pathological sequences and complications of the childbearing act at all periods. He said that when he first went into practice he found that about one-half of the patients either would not, or could not, nurse their babies—the majority could not. At the present time, however, he found that the proportion of women who did not nurse their babies had been materially reduced by about 25 or 30 per cent. But it should be remembered that a considerable proportion of women among the wealthy classes could not nurse their children. In his experience he had found that the women who could not nurse their babies belonged to one of two classes. There was the type of women who were anemic and lackadaisical, fortunately becoming quite rare at the present time. Then there was another type of women, so full of the affairs of a complicated household, committees, etc., that her natural functions were imperfectly performed. He believed that if the general practitioner would unite with the obstetrician and regulate this excessive nervous and physical activity of the women of the present hour, as well as superintend the

rearing of the young girls, a much healthier and finer specimen of womanhood would result.

Dr. William M. Polk said he wished to take exception to one remark of Dr. Winters, that mother's milk could be withdrawn from the child when two months old. That, in his opinion, was wrong; the child should get the mother's milk for a longer period of time. Cow's milk was not so good for the infant as the mother's. The large majority of the people really desired to care for their young, but the conditions of modern life made it oftentimes difficult to perform that all-important function, and they were driven to use an artificial product. He asked if it was not wonderful that, as the women lived in the cities to-day, they had any milk at all. People who wanted to speak on and agitate sociological problems should begin their work with babies, not along the line of pasteurized milk or artificial foods, but along the line that Nature intended, to help the weak and struggling parent to give proper time and proper care and attention to the functions of motherhood.

Dr. Edwin B. Cragin said that nursing was rapidly becoming a lost art. When he looked back over ten years of his work at the Sloane Maternity Hospital, he found that more babies required artificial feeding to-day than ten years ago. Whether the struggle for existence was more severe to-day or not, he did not know, but he rather inclined to this opinion. This was particularly so among the tenement house class. Of course, there existed at all times those who did not wish to nurse their infants. It seemed to him that it was extremely important that the general practitioner and the obstetrician should unite in impressing upon these people the importance of the mothers nursing their babies. No prescribed milk was equal to the breast milk except in exceptional cases. During the winter raw milk he considered better than pasteurized milk. Raw, clean milk was better than pasteurized clean milk. If the milk was dirty, he preferred pasteurizing it rather than giving it raw. In summer, on the other hand, when the people could not be sure of the character of the milk, he preferred using pasteurized milk. Personally he believed in the top milk, given raw if it was clean. He also believed in giving some preparation to peptonize it. In other words, what he preferred above all else, was top milk diluted and peptonized. Barley water was a better diluent than plain water during the first months of life.

Dr. Henry M. Painter said that it was an indisputable fact that there were a number of women in the higher social walks of life who were not only willing, but eager, to nurse their babies, and this number was increasing constantly. A few years ago it was difficult to persuade a woman to nurse her baby; but as time went on this changed, and to-day one practically never was called upon to urge this upon the mother. He said he had a distinct message to give the members, based upon practical experience, in private and not in hospital practice. They had been told constantly that it was perfectly useless to attempt to get a woman who was mixed up in the whirlpool of social life to nurse her baby. Also, even though she was willing, the life of excitement produced so many changes in the quality of the milk that the child was not properly nursed. This he had not found to be the case. He had had no difficulty from that source. This was a point that he wished particularly to emphasize because it had been brought forth as an argument in favor of the institution of artificial feeding.

Dr. Asa Barnes Davis spoke of the influence of the nursing babe upon the mother herself, the resulting contraction of the uterus induced by the nursing infant at the breast. This was a point that should be considered more in deciding whether or not a woman should nurse her offspring. He agreed that there was an increasing tendency among women in the better walks of life to desire more and more to nurse their children.

Dr. George L. Brodhead said that in looking over the records of patients years ago, he had found that from 30 to 40 per cent. of them would not, or could not, nurse their babies; but he was sure that during the past few years the percentage of women who could and would nurse their babies had been considerably increased. Because a woman had failed in her endeavor to nurse the first child did not mean that she would fail all other children born to her. Among the requisites for the successful nursing of infants were calm and rest of the patient's mind. He believed that the physician should insist upon every mother nursing her infant, at least for a period of one or two months; the longer the mother nursed her child of course the better.

NEW YORK ACADEMY OF MEDICINE

Stated Meeting, Held February 4, 1909.

Dr. Algernon T. Bristow in the Chair

THIS MEETING WAS HELD UNDER THE AUSPICES OF THE SECTION ON MEDICINE.

Cardiac Insufficiency.—Dr. Walter Mendelson read this paper. He said that while the valvular troubles perhaps held the front rank in interest in the study of the heart, there were certain non-valvular troubles which were also of great interest to the physician and of high importance to the patient, and it was to the general consideration of these that he invited attention. In taking cardiac insufficiency for his theme, he considered it in its broader aspects, and looked upon it from the vantage ground of pathological physiology and illustrated this point of view from clinical examples. Cardiac insufficiency had taken place when the work done by the heart was inadequate for the proper demands of the economy, or when the pump ceased to supply sufficient fluid to perfectly irrigate the required area. The ultimate causes of myocardial insufficiency must be sought, first, in all those agencies that weakened the heart directly, such as the acute infections, nephritis, diabetes, anemia, syphilis, and tobacco; secondly, in all those agencies that placed upon the heart either a prolonged or sudden degree of overwork, to which the myocardium was incapable of lastingly responding. Under this latter category must be ranged uncompensated valvular defects, arteriosclerosis, pericardial adhesions, pulmonary sclerosis and emphysema, pleuritic exudates or adhesions, pneumothorax, obesity, excessive beer-drinking, over-eating, the strain of athletes, overwork of porters, mountain climbers, soldiers, sailors, etc. Often two or more sets of causes were combined. Excessive exertion over-distended the heart's cavities, with consequent over-stretching of the muscle fibers, and this ended in molecular deterioration. This last was true generally of elastic bodies. Insufficiency once begun, contributory causes quickly set in to increase it, and chief among these were the alterations of tissue consequent upon those metabolic changes which a disturbed circulation dragged in its train. A vicious circle was set up, the weakness of the heart induced faulty metabolism, and the products of this faulty metabolism in their turn augmented the cardiac degeneration. In general terms, therefore, it might be said that the cause of all cardiac degeneration lay in a lack of balance between the nutrition of the heart on the one side, and the amount of work it was obliged to perform on the other. So soon as the expense began to exceed the income, bankruptcy began. The work of the heart was determined by three factors; firstly, by the amount of the diastolic filling; secondly, the force with which the heart contracted upon its contained blood, and thirdly, the peripheral resistance to be overcome. It was evident, therefore, that insufficiency might

arise either from the side of the heart itself, or from the side of peripheral resistance presented to it. If the sequence of events which occurred when the heart was weakened was followed, it would become evident that while these events must vary according to which side was affected, the final results would be the same. Though clinically it might not be possible to say on which side the trouble began, it was nevertheless of interest to analyze the conditions that obtained. If the left ventricle was weakened it was unable to expell from its cavity the quantity of blood that had flowed into it during the diastolic filling. In consequence the pulse would have little volume and the tendency of the systemic blood pressure would be to be low. The left auricle, owing to an incompletely emptied ventricle, would be unable in its turn to empty itself completely, with the result that a backing up of blood in the pulmonic vessels occurred. This latter congestion in turn reacted upon the right ventricle, causing an over-distension, and this again upon the right auricle, and so finally upon the systemic veins, leading to congestion (with enlargement) of the liver, of the kidneys, and of all the abdominal organs. If the trouble began in the right heart, due to some obstruction in the pulmonary circulation, the course was practically the same. The final result of insufficiency of either half of the heart was diminished filling of the down-stream circulation and damming back of the up-stream current. As an illustration of cardiac insufficiency beginning in the right heart, he related a case. Dilatation and consequent over-distension might, in the healthy heart muscle, be overcome, provided the condition was but temporary; if, however, it was long continued, it was the fruitful source of myocardial degeneration.

Of all the symptoms of cardiac insufficiency, dyspnea, or air hunger, was the most prominent, as it was also the most general. Haldane and Priestly had shown that the sensation of dyspnea arose not from a lack of oxygen in the blood, but from an accumulation of carbon dioxide. The nerve center of respiration was not so sensitive to changes in the oxygen tension of the blood as it was to an increase in the carbon dioxide tension. For the oxygen tension in the air cells might be reduced from the normal of 20 to 8 per cent. without effect upon respiration; but an increase of but .5 per cent. in the carbon dioxide tension of the pulmonary air cells, with a corresponding increase of carbon dioxide in the blood circulating through the respiratory center, so stimulated this center that the volume of respired air was doubled. It had been shown by v. Basch that in cardiac dyspnea, or cardiac asthma, the distention of the alveolar capillaries resulted in pulmonary swelling and rigidity, and that the dyspnea was not due, at least not primarily, to the filling of the alveoli with a liquid transudate, the result of edema. He showed that a considerable amount of water could be introduced into the lungs of a dog whose heart was healthy, without producing dyspnea. A striking feature of cardiac asthma was the disturbance of the usual respiratory rhythm: inspiration was quick and short and shallow, and all the agony seemed to be concentrated in efforts to expel the air from the lungs. It was a peculiarity of cardiac dyspnea that it was apt to occur at night, and the explanation of this was not clear. Knowledge of pain as a prominent symptom of cardiac insufficiency stood on a less satisfactory footing than did that of dyspnea. Pain could not be so well brought under the domain of experimental pathology. Most patients suffered at some time from pain; this might range from a slight precordial fullness to the agonizing seizure of angina pectoris. Exertion was the usual excitant. The cause of pain was most probably to be sought in an ischemia of the ramifications of the sympathetic fibers supplying the heart. There was one peculiarity of angina pectoris which differed from any other pain, namely, the *angor animi*, that "anguish of the soul" which was so well described by an unknown writer in his letter about his own case addressed to Dr. Heberden, when he said that he experienced "an universal pause within me of the operations of Nature." Belching was a frequent accompaniment of the anginoid attacks. From his own observations he was inclined to think that the belching of gas was not always the cause of an attack but a concomitant, though doubtless it might intensify it. Two Dublin physicians, Stokes and Adams, described a symtom-complex; with syncopal or epileptiform attacks was associated a very slow pulse, sometimes as low as five to the minute. To understand the nature of this trouble, it was necessary to consider the nature of the heart itself. The various theories of the cause of the beat of the heart were considered. The view held at the present time by most observers was that the beat of the heart, while certainly affected and modified by nervous influences, was due primarily to an inherent rhythmic contractitility of the heart muscle itself. In conclusion Dr. Mendelson gave a few typical cases of the different forms under which cardiac insufficiency might show itself.

Some Recent Clinical Improvements in Methods of Studying the Diseased Heart.—Dr. WALTER B. JAMES spoke of the studies of many men which had resulted in the use of certain instruments of precision for the clinical study of diseases of the heart, and particularly of the general subject of cardiac dilatation. He showed a few tracings and the instruments themselves. The instrumental study of the circulation had always had a "black-eye." The sphygmograph really gave nothing more than what was given by the finger upon the pulse; it gave the pulsation, the dicrotic wave, the character of the downfall of the artery, all of which could be learned with the finger on the artery. Those who used the sphygmograph came to grief in trying it from the quantitative standpoint; however, it did give results from a qualitative standpoint. To get a tracing was comparatively easy, but to interpret the tracing was not so simple. The tracings he showed and explained were taken from some of his cases in Roosevelt Hospital.

Dr. HERRICK and Dr. JANEWAY showed three tracings taken from a woman with Stokes-Adams disease.

Dr. HAVEN EMERSON said that cardiac insufficiency could be produced in the laboratory by five means. (1) The valvular lesions could be produced and cause a moderate cardiac insufficiency. If the mitral valve was cut, there would immediately follow a cardiac insufficiency with a dropping of the blood pressure and a distention of the right side of the heart, with venous engorgement. (2) Increased peripheral resistance was probably a common cause of cardiac insufficiency, especially where there was an arterial sclerosis. Heavy doses of adrenalin in small animals was a way to produce this artificially. (3) By producing cerebral anemia; this caused a reflex and not a direct vasoconstriction. (4) By producing a myocarditis. One could produce this lesion by the injection of alcohol into the heart muscle. (5) By the production of pericardial infusion. This would cause a cardiac insufficiency. The value of these procedures were sufficiently definite and accurate to be of value as a means of teaching physiology and medical diagnosis, teaching a method by which cardiac cases could be observed and studied clinically.

Dr. LEWIS A. CONNOR said that all had noticed the diversity of the clinical pictures as shown in cases of cardiac insufficiency; therefore, it should be treated more than as a single entity. There was an increase in the rigidity of the lungs in these cases. An important factor in cardiac insufficiency was the over-distention produced by the low position of the diaphragm; the low position of the diaphragm played an important part in interfering with the venous return. With the advent of the sphygmograph Dr. Connor said there had been a tendency to give up digitalis and to rely upon the vaso-dilators, the belief

being that this drug was not indicated. This was an error, for digitalis was of great value in many of the cases of cardiac insufficiency.

Dr. T. B. Barringer said that the necessity of taking sphygmographic tracings was not sufficiently recognized by the members of the medical profession. He spoke of an instrument in use in Bellevue, costing less than one hundred dollars, which was mounted on a stretcher and wheeled from bed to bed, and he told of the practical results obtained by its use during the past six months. It was of special value in the cardiac arhythmias. In aortic lesions it was not of so much value except in those cases where the right heart was dilated.

Dr. Janeway said that the use of these instruments gave no additional points for treatment at present, although he believed that in time they would. There should be more and more refined methods for studying these cases. Physiologists should devote their energies more largely to newer methods of treatment in addition to what they were doing in the diagnostic methods.

Dr. L. F. Bishop said that the term "elasticity" should be dropped and the term "tone" substituted. More attention should be paid to the tone of the heart and blood vessels. He had found that cases with a high blood pressure had not had the pressure further elevated by the use of digitalis. In the low tension cases, however, the pressure was thus raised. These patients improved under the use of digitalis. It was at times dangerous to resort to the use of vasodilators in these cases. Dr. Bishop presented the instrument with which he measured the blood pressure.

THE WILLIAMSBURG MEDICAL SOCIETY.

Stated Meeting, Held December 14, 1908.

Dr. Leon Louria in the Chair.

The Diagnosis and Therapy of Pulmonary Tuberculosis.—Dr. S. Adolphus Knopf of New York read this paper. He said that it was hardly necessary to review all the well-known points in the diagnosis of incipient tuberculosis. He thought it more profitable to allude to a few little-known diagnostic points that were of considerable practical value. On questioning the patient or his friends one was sometimes able to gather that he had recently undergone a change of character: he had become irritable, or morose, or had merely lost all desire for pleasure. In girls a diminution in the menstrual flow was an early symptom. In questioning the patient as to his weight, it was important to determine when his weight had been best, how much he had weighed one year before, and so make a comparison of his weight with his height. In early cases of tuberculosis there was frequently noticed a peculiar brittleness of the hair. The speaker did not put any stock in the alleged asymmetry of the lobes of the ears. A dilated pupil on the side of the disease from pressure of enlarged glands on the pneumogastric was a frequent sign. There was occasionally noticed a reddish-blue line along the gums. It was important to determine whether the voice was as clear as it had always been. In taking the anamnesis, which was a most important part of the examination, it was important to determine how many children the patient's mother had borne, and whether he was one of the earlier or later children. It was significant that the later borne children were the ones most prone to tuberculosis. This fact had both a physical and an economic basis. It was desirable to avoid asking the patient if his father died of tuberculosis. Apart from the fact that such questioning needlessly scared the patient, it added nothing to the diagnosis. There were only sixty recorded cases of direct bacillary transmission of the disease. It was more important to question the patient as to whether he had been associated with any one who had had tuberculosis. Direct drop infection was an important consideration, more so than the danger of infection from dry sputum. The speaker next dwelt upon certain salient features in the physical examination of the patient. On inspection it was important to note any depression in the supra and infraclavicular regions, and any undue prominence of the scapulæ. The value of palpation was not to be underestimated. The presence of rivulets of perspiration in the axillary region was a frequent concomitant of tuberculosis. It was necessary for the examiner to concentrate his mind on the examination. Fremitus was both objective and subjective. The bass voice was better than the high-pitched voice. There was a slight physiological increase of fremitus on the right side. By subjective fremitus was meant the fact that the patient could feel his own voice more on one side than on the other; the side in which it was louder corresponding to the diseased lung. In percussing the clavicle it was necessary to percuss the external, middle, and internal thirds. In percussing the supraclavicular region it was necessary to percuss both up and down and from side to side, and also during deep inhalation. In auscultation the ear was better than the stethoscope. One was to listen first to the normal breathing, then to exaggerated breathing, and then to the whisper. A prolonged roughened expiratory murmur was almost pathognomonic of tuberculosis. Later stages revealed moist râles, crackling râles, and a blowing murmur. The x-rays were only of corroborative value, and sometimes gave a mistaken idea. An old pneumonia or a thickened pleura gave a shadow. Of great value was the picture of the irregular excursion of the diaphragm. In comparing the various diagnostic tests with the aid of tuberculin, the speaker expressed his preference for the least dangerous, namely, that which consisted in the use of Moro's ointment, made up of equal parts of old tuberculin of Koch and lanolin. A piece of this the size of a pea, when rubbed into the skin, produced in twenty-four to thirty-six hours an acne-like eruption. In the therapy of the disease the problem was to adapt the sanatorium treatment to the home. In this the essential factor was the complete control of the patient. The speaker discussed the various means of applying aerotherapy in the home, with the aid of the window tent. The patient was never to be allowed to exercise when he was tired, nor to exercise to the point of fatigue. When the patient did not feel like taking exercise, massage was better. In following out solar therapy it was necessary to have the patient's head always in the shade; otherwise he would suffer from headache. Hydrotherapy was alluded to. In the dietetic management overfeeding was to be avoided, but three square meals were necessary. If these were not enough, then one or two eggs were to be taken after each meal. The dietary should include spinach, lentils, cauliflower, plenty of grapes, milk with salt, and raw scraped beef. The best cough medicine was discipline. Before the speaker prescribed a cough mixture he advised the use of the Beverley Robinson inhaler, with a mixture consisting of eucalyptus, menthol, and spirit of chloroform, of each one dram and a half. Five or ten drops of this was to be inhaled for ten or fifteen minutes at a time. In place of this mixture he sometimes used eucalyptus, creosote, and rectified spirits. In the internal administration of creosote it was desirable not to give large doses. In the treatment of hemorrhage the previous warning of the patient was a help. Habitual constipation was controlled by the drinking of plenty of water. Taken in small swallows, so as to stimulate peristalsis. Massage was a help. The unhygienic water-closet was a common cause of constipation. Diarrhea, when due to injudicious feeding, was treated best by cleaning out the intestinal tract. If the diarrhea was a result of the tuberculosis it was controlled

best by a diet of rice, milk (if it tended to constipate), chocolate, cocoa, stale bread, and zwieback. Absolute rest was to be enforced, and for pain hot compresses were to be used. The most serviceable drugs were tanin, gallic acid, opium, and bismuth. Hyperidrosis was best controlled by dietetic treatment. The patient was to have a glass of milk and a piece of toast or a sandwich at hand, in order to get the needed refreshment during the depressing sweat.

Pathological Society of Philadelphia.

At a stated meeting held January 28 Dr. H. E. Allyn presented a specimen of "Carcinoma of the Stomach," in which the growth involved the lesser curvature, death resulting from peritonitis in consequence of perforation. The pancreas was in part indurated, but presented no involvement in new-growth, although a positive Cammidge reaction had been obtained twice during life. Dr. A. O. J. Kelly presented two specimens of "Carcinoma of the Bladder with Consecutive Pyonephrosis." Both were examples of epithelioma. The ureters were greatly dilated, in the one specimen attaining the lumen of the small intestine. Dr. Kelly exhibited also a specimen of gangrene at the apex of the lung, with extensive cavity-formation, associated with caseous pneumonia of the middle lobe and granular and ulcerative tuberculosis in the inferior lobe. He exhibited further a specimen of hypernephroma at the upper pole of the kidney, an altogether accidental finding, wholly unattended with symptoms during life. Dr. M. Howard Fussell exhibited a specimen of "Primary Carcinoma of the Gall-bladder." During life the abdomen was greatly distended, yielding a tympanitic percussion-note from floating up of the intestines on the contained ascitic fluid. There was also pleural effusion. On post-mortem examination the liver was found enlarged and fatty and the seat of a metastatic growth, while the omentum was drawn up and involved in miliary carcinosis. The gall-bladder was the seat of apparently a primary growth, and it was filled with gallstones. Drs. George I. MacLeod and F. H. Laer presented a communication entitled "Septicemia Caused by the Pseudodiphtheria Bacillus, with Report of a Case." The patient was a man from whose blood cultures of pseudodiphtheria bacilli were obtained during life. Injections of diphtheria antitoxin were given, but without curative result. The question of the relationship between diphtheria bacilli and pseudodiphtheria bacilli was discussed, and the opinion expressed that the two forms belong in the same group, differing only in the production by the former of a specific toxin. Drs. R. S. Lavenson and H. T. Karsner presented a communication entitled "Periportal Fibrosis of the Liver in Tuberculosis." Histologic studies were made in fifty consecutive fatal cases of pulmonary tuberculosis, various grades of perilobular fibrosis being found in all, with actual tubercles in only a few instances. A comparative study was made in forty other cases of varied kinds, but not tuberculous, and in these similar fibrosis was found in a much smaller percentage of cases. Experimental evidence was cited in support of the view that the lesions are in some way related to the tubercle bacillus or the toxins elaborated by it. Dr. E. H. Goodman read a paper entitled "The Rôle of the Saliva in Digestion." He pointed out the part played by the saliva in the solution of portions of the food, thus facilitating the appreciation of taste, in the lubrication of the bolus, thus facilitating deglutition, in neutralizing acids and in diluting alkalies, and finally in initiating diastatic digestion of carbohydrates. Dr. E. B. Krumbpaar presented a communication entitled "Tumor of the Hypophysis Cerebri in Relation to Acromegaly." He reported a case in which growth was attended with symptoms of brain-tumor and not with those of acromegaly.

THE PRINCIPLES AND TECHNIQUE OF THE WASSERMANN REACTION AND ITS MODIFICATIONS.*

BY HOWARD FOX, M.D.,

NEW YORK.

THE subject of the serum diagnosis of syphilis may appear at first glance to be somewhat complicated, owing to the multiplicity of the terms that are used. The principles of the reaction can, however, be easily mastered, whereas the practical knowledge, owing to the many sources of error, can only be acquired after a considerable amount of experience.

In order to understand the Wassermann-Neisser-Bruck reaction, as the serum test for syphilis should properly be termed, it is necessary to understand the principles of hemolysis and of the Bordet-Gengou phenomenon. By hemolysis is meant the power possessed by the serum of one species of animal to dissolve the corpuscles of another species. If, for instance, fresh serum from a rabbit is placed in a test tube, and sheep's corpuscles are added, the serum will be seen to dissolve to a slight extent the corpuscles of the sheep. If the same rabbit is now treated by several injections of sheep's corpuscles, and its serum withdrawn and placed in a test tube, it will be found that this power to dissolve the sheep's corpuscles has been greatly increased. The rabbit is now said to be immunized against sheep's corpuscles. By this we mean that a certain substance has been artificially formed in the rabbit serum to which the name of hemolytic amboceptor,† or immune body, has been given. Heating to 56° C. for a half-hour does not destroy this substance, therefore it is said to be thermostabile. Hemolysis depends not only upon this hemolytic amboceptor, but also upon another substance called complement, which is present in all normal fresh sera, and which is destroyed by heating to 56° C. for a half hour. It is said to be thermolabile. The three substances, corpuscles + hemolytic amboceptor + complement, constitute what is called a hemolytic system, and hemolysis can take place only when all three are present.

Closely analogous to a hemolytic system is what may be termed a "bacteriolytic system," consisting of (1) a bacterium, corresponding to the corpuscles in the hemolytic system, (2) a bacteriolytic amboceptor (or antibody) corresponding to the hemolytic amboceptor, and (3) complement, similar in both systems. Before proceeding to discuss this so-called bacteriolytic system, it is necessary to explain the terms antigen and antibody. An antigen is any substance (bacteria, corpuscles, body cells, etc.) which, when introduced into an animal, is followed by the formation of antibodies. The sheep's corpuscles in the case of the hemolytic system and the bacteria in that of the bacteriolytic system are examples of antigen. The substances formed by their entrance into the animal are antibodies or amboceptors. Strychnine, for instance, though an injurious substance, is not an antigen, as its entrance into the body is not followed by the formation of antibodies. Furthermore, it should be said that the term antibody does not necessarily imply a substance that is protective, such as an antitoxin.

Returning to the bacteriolytic system, and taking a specific instance, we will use for antigen an emulsion of the typhoid bacillus; for bacteriolytic amboceptor or (antibody) the serum of a patient suffering from typhoid fever; and for complement, normal fresh serum, preferably from a guinea-pig. If these three substances, typhoid bacilli + typhoid amboceptor + complement, are placed in a tube for half an hour at body temperature, a union will take place just as it did in the case of the hemolytic system. The bacteria, instead of the corpuscles, are dissolved. Unlike what occurs in the hemolytic system, the union of these three substances will not be followed by any visible change. It cannot be told from the appearance of the tubes whether or not the bacteria have been dissolved. In the case of the corpuscles, solution was most apparent, the tubes changing from an opaque to a clear red color upon hemolysis. In other words, in the hemolytic system there was an indicator to show that solution of the corpuscles had taken place, no such indicator being present in the case of the bacteriolytic system.

Bacteriolytic System consists of	Hemolytic System consists of
1. Bacterium (antigen).	1. Corpuscles (antigen).
2. Bacteriolytic amboceptor (antibody).	2. Hemolytic amboceptor (antibody).
3. Complement.	3. Complement.

The reaction discovered by Bordet and Gengou in 1901 utilizes the phenomenon of hemolysis to show that a union actually can occur between the three components of a bacteriolytic system. This reaction depends upon the so-called principle of the fixation (anchoring or binding) of the complement, and is carried out as follows: The three components of a bacteriolytic system, such as typhoid bacilli + typhoid antibodies (serum of patient to be tested) + complement, are placed in a test tube and incubated at 37° centigrade for a half hour to allow them to unite. To the same tube are then added two of the elements of a hemolytic system, namely, hemolytic amboceptor and sheep's corpuscles, and the mixture again placed in the incubator. If now there has been an actual union of the first three substances,

*Read in part before the Medical Association of the Greater City of New York, January 18, 1909.

†The term amboceptor means that this substance has an affinity on the one hand for corpuscles, and on the other hand for complement. The complement is so called because it completes the action of the amboceptor.

that is, if the complement has been fixed or used up by uniting with the other two substances, there will be no complement left to unite with the other two parts of the hemolytic system, and consequently no hemolysis will occur. If, on the other hand, no union of the first three substances had occurred, complement will be available to unite with the other two parts of the hemolytic system, and consequently hemolysis will take place. In other words, the absence of hemolysis denotes a positive reaction, *i. e.* the antibodies for which we were testing are present. In the case in question, the patient was suffering from typhoid fever. The occurrence of hemolysis, on the other hand, signifies a negative reaction, *i. e.* the antibodies were not present. In that case the patient was not suffering from typhoid fever.

The principle of the fixation of complement can be illustrated by a swinging pendulum, as shown in Fig. 1. The pendulum representing the complement swings to one side and completes the bacteriolytic system, or to the other side and completes the hemolytic system. In the first case the result is no hemolysis. In the second case hemolysis occurs.

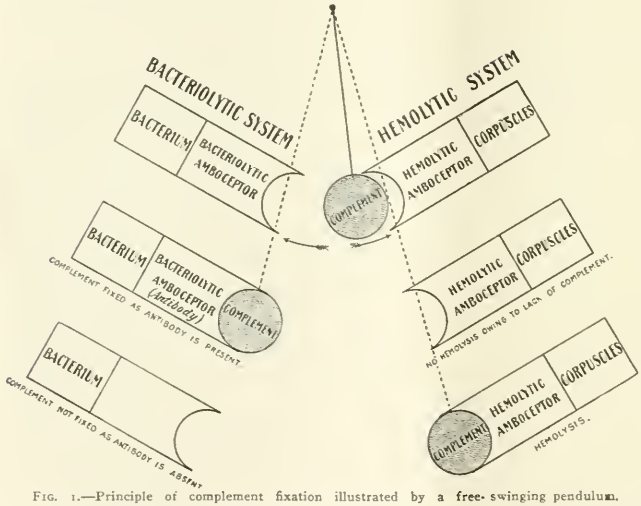

FIG. 1.—Principle of complement fixation illustrated by a free-swinging pendulum.

It may be asked why it is necessary to use guinea-pig serum for complement when there is complement already present in the serum of the patient to be tested. The answer is that the latter is an unknown and variable quantity. On this account we destroy the complement before beginning the test, by heating the patient's serum to 56° C. for a half hour. We then add for complement a measured amount of guinea-pig serum.

The principle of Bordet and Gengou,[1] which has been used since its discovery as a means of diagnosis in many bacterial diseases, was applied to syphilis in 1906 by Wassermann, Neisser, and Bruck.[2] By this test the presence not only of antibodies, but also of antigen could be demonstrated. As a culture of the organism of syphilis (*Spirochæta pallida*) could not be obtained, it was necessary to use as antigen an extract of syphilitic tissue known to contain the organism in large numbers. For this purpose the liver of a syphilitic fetus in which the spirochetes could be demonstrated was employed. The same principles, as explained above to detect the presence of typhoid antibodies, were then applied to syphilis, the extract from the syphilitic fetus being substituted for the culture of the typhoid bacilli and the syphilitic patient's serum for that of the patient suffering from typhoid.

The extract of the fetal liver as first used by Wassermann was made with physiological salt solution, to which carbolic acid was added as a preservative. While good results were obtained from such an extract, it was found to be liable to sudden deterioration in strength. An extract that proved reliable and effective on a certain day might on the following day become entirely worthless.

Not only extracts from syphilitic livers, but also from normal livers (Marie and Levaditi[3]), and, in fact, from a large variety of normal organs were found available as "antigen." Extracts of guinea-pig liver (Landsteiner[4]), and even of tumors (Weil[5]) were found suitable for this purpose. It was later discovered by Porges and Meier[6] Landsteiner, Müller and Pötz,[7] and by Levaditi and Yamanuchi,[8] working independently, that the active principle could be extracted from the syphilitic liver by alcohol. This showed that the active principle was a lipoid and not an albuminoid substance, as had previously been supposed. Experiments were then made to substitute as the antigen various lipoid substances in place of the syphilitic liver extract. Lecithin was thus first used by Porges and Meier, with results approximately similar to those obtained by using the extract. Numerous other lipoid substances and salts were then tried with more or less good results, among them sodium glycocholate and sodium taurocholate (Levaditi and Yamanuchi), sodium oleate (Sachs and Altman[9]), cholesterin and vaselin (Fleischman[10]), sodium cholate (Noguchi[11]). Cholesterin was, however, found by Levaditi and Yamanuchi and by Noguchi to be inactive. Noguchi found that acetone soluble and acetone insoluble fractions of the alcoholic extract of normal or syphilitic tissues, such as blood serum, blood coagula, liver, kidneys, etc., possessed antigenic properties.

By using an alcoholic extract of guinea-pig heart, in comparison with syphilitic liver extract, Landsteiner and his associates obtained identical results. Even Meier,[12] in a recent communication from the laboratory of Wassermann, admits that the guinea-pig extract of Landsteiner serves as a perfectly reliable substitute for the extract of syphilitic liver. As between the watery and alcoholic extract of the syphilitic fetal liver, it seems certain, as Marchildon[13] has recently shown, that both are equally potent. As the alcoholic extract can be kept for a much longer time, it should for this reason be preferred.

The discovery that various substances in no way related to syphilis were able to combine with the syphilitic antibodies, showed that the Wassermann

reaction could no longer be considered as a true antigen-antibody reaction. While this is admitted by all, including Wassermann himself, it does not in any way lessen the great practical value of the test. The reaction must be considered as a union taking place between certain lipoid substances and the antibodies existing in syphilitic blood.

The five substances used in performing the Wassermann reaction and the steps necessary to prepare them are as follows:

1. *Antigen.*—The liver of a syphilitic fetus is cut in fine pieces, ground in a mortar, and placed in a flask. Alcohol is then added in the proportion of 5 c.c. for each gram of liver substance. The solution is then shaken from time to time, a shaking machine being unnecessary for this purpose. After a few days of extraction the solution is ready to be tested. It is kept at room temperature and will remain for a considerable time (several months) without deterioration. To ascertain the necessary dose of the extract it is tested in varying amounts with a series of cases known to be positively syphilitic. That

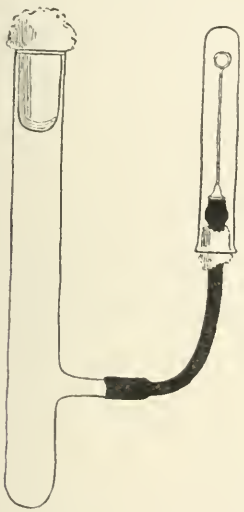

Fig. 2.—Blood-collecting tube; one-half natural size.

amount that will give complete inhibition of hemolysis, when 0.2 c.c. of the patient's serum is employed, will be the required dose. At the same time there must be no inhibition of hemolysis in the control tube containing the hemolytic system + extract, even when double the dose of extract is used. In place of the liver extract a suspension of crude lecithin can be used. The latter substance, as prepared and titrated by Noguchi, has been used by me up to the present time as antigen.

2. *Antibody* (patient's serum).—The blood of the patient to be tested can be collected directly from a vein or from a puncture of the finger or ear. The frequent necessity of repeating a test makes it desirable to have a plentiful amount of serum. For this reason I strongly favor obtaining the blood from a vein such as the median basilic, which is easily done by using the little apparatus devised by Noguchi, shown in Fig. 2. This consists simply of a test tube having a small outlet at the side connected by rubber tubing with the needle. The latter is covered by another small test tube for protection. The tubes are then sterilized in the autoclave. The writer uses needles that can be easily detached from the tubing, and advises that the needles be cleansed with alcohol immediately after use. A little practice will make it possible to collect from 6 to 10 c.c. of blood with practically no pain or inconvenience to the patient. Before puncturing the vein, several turns of a bandage are made above the elbow, and the patient is told to clench the fist. A quick plunge of the needle is then made in the direction of the blood stream. The tubes are then slanted, and the blood allowed to clot firmly. After remaining for an hour or more at room temperature, the tubes are placed in the ice chest until the serum has been expressed, requiring, as a rule, about twelve hours. The serum is then pipetted or drawn off and inactivated by heating in a water bath at 56° C. for a half hour. It is then available for immediate use, or it can be used as late as the third day after its collection. If the serum is turbid, due to the presence of corpuscles, it must be centrifugalized until clear.

3. *Complement.*—A guinea pig is bled from the jugular or carotid into a large Petri dish. The blood is allowed to clot, and after remaining for an hour at room temperature is placed in the ice chest until the serum is expressed. The serum is then poured off into a sterile tube and kept in the ice chest until ready for use. Complement is active for two or three days, but is preferably used within twenty-four hours after it has been obtained. The writer's custom is to bleed his animals late on the afternoon of a certain day, using the serum on the following morning or afternoon.

4. *Hemolytic Amboceptor.*—A rabbit is injected subcutaneously, intraperitoneally or intravenously several successive times with washed, but diluted, sheep's corpuscles. A good plan is to give four injections at intervals of five days in dose of 2, 4, 8 and 16 c.c., respectively. The blood is then withdrawn nine days after the last injection. By this time the serum will have, as a rule, the required amount of amboceptor. The blood is drawn from the carotids into sterile tubes and allowed to clot. The serum is then removed, inactivated and standardized. By standardizing is meant the determination of a so-called *unit* of *amboceptor.* This refers to the smallest amount of the rabbit's serum that will completely hemolyze 1 c.c. of a 5 per cent. suspension of sheep's corpuscles when placed at 37° C. for 1 hour. For the tests two such units are employed. The amboceptor can be kept in the ice box for weeks and months, though it gradually tends to lessen in strength.

5. *Sheep's Corpuscles.*—Blood is obtained either from the jugular vein of a sheep by means of a canula or from a slaughter house when the animal's throat is cut. It is collected in a sterile beaker and defibrinated by stirring with a glass rod. The corpuscles are then washed free of serum by adding normal salt solution and centrifugalizing several times. The salt solution is then poured off and the corpuscles diluted with more normal salt solution to form a 5 per cent. suspension. Of this suspension, 1 c.c. is used for each tube. The corpuscles may also be used in their original volume, i. e. after washing no suspension in salt solution is made. One drop of this original mass of corpuscles serves for each tube. The corpuscles can generally be used four or five days if kept in the ice chest. After this they begin to be hemolyzed, as is shown by a dark-

ening of the original bright red color. They are then unavailable for the test.

The practical performance of the Wassermann test requires a laboratory equipped with a thermostat, ice chest, centrifugal machine, water bath, and, in addition, an antoclave, if the tubes shown in Fig. 2 are employed. A large number of small test tubes are needed, and a considerable number of 1 c.c. pipettes (preferably Mohr pipettes graduated in a hundred divisions to the tip). It is of great importance that both tubes and pipettes should be thoroughly cleansed in running water after use and subjected to a high temperature in the antoclave or other sterilizer before they are again used. It is not essential that the tubes should be plugged with cotton. It is, however, necessary for them to be perfectly clean.

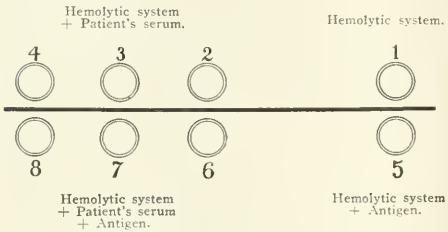

Fig. 3.—Illustrating controls that are used.

The arrangement of the tubes used for the test, including the necessary controls, is shown in Fig. 3. Tube No. 6 contains serum of a patient to be examined. No. 7 contains the serum of a patient known to give a positive reaction, and tube 8 a serum known to give a negative reaction. The three tubes 6, 7 and 8 receive all five substances necessary for the reaction. All of the other tubes are controls. Tubes 2, 3 and 4 contain the hemolytic system+the patient's serum, it being of course necessary to have a separate tube for each separate serum. Tube 5 contains the hemolytic system+the antigen (extract or lecithin). Complete hemolysis must take place in all of these control tubes. Tube 5 is necessary to show that the antigen of itself does not bind complement and so prevent hemolysis. In the same way tubes 2, 3 and 4 show that the patient's serum of itself does not bind complement. In case the patient's serum proves to be anti-hemolytic of itself, the test must be repeated and the serum used in a smaller amount, *e. g.* 0.1 c.c. instead of 0.2 c.c. Tube 1 shows that the hemolytic system is in "working order." While it is essential in testing a given serum to employ as controls a known positive and a known negative serum, it is also desirable to test a large series of cases simultaneously. This allows a comparison which aids in making the results more trustworthy.

In performing the test 0.1 c.c. of complement (invariable dose), 0.1 c.c. of serum (usual dose), and antigen (dose varies according to the preparation, average being 0.2 c.c.) are placed in the tubes, and 1 c.c. of physiological salt solution is added. The tubes are then shaken and kept in the thermostat or water bath for three-quarters of an hour. Two units of amboceptor, and either 1 c.c. of the corpuscle suspension or one drop of corpuscles, according to choice, are added. The tubes are then shaken and again incubated and observed at frequent intervals. The final results can be recorded after three hours of incubation. The controls are generally found to be hemolysed within a half hour, tube No. 1 being the first and tube No. 5 generally the last to be entirely hemolysed. A negative result is denoted by complete hemolysis. A positive result is shown by inhibition of hemolysis, which, according to its degree of intensity, can be classed as positive, strong positive or weak positive. For recording results a chart devised by Dr. Wood McMurtry will be found of very great convenience.

In performing the Wassermann test the body fluids usually employed to show the presence of the syphilitic antibodies are the blood serum and spinal fluid. The presence of antibodies have been reported in the milk by Bab and Plaut,[14] and in the urine by Blumenthal and Wile.[15] The latter observers, in a series of fifty cases in which the serum and urine were tested simultaneously for antibodies, found that a stronger reaction was given by the serum than by the urine. Furthermore, in a series of cases giving a strong reaction, the urine of itself showed anti-hemolytic properties. In a later report of a hundred cases by Wile[16] it was found that 2 per cent. of the cases gave positive reactions with the urine and negative reactions with blood serum. From this the writer concludes that the "diagnostic value of the reaction must for the present be viewed with caution."

As the Wassermann reaction is at best a rather complicated procedure, requiring special laboratory facilities and a considerable expenditure of time, it is not surprising that attempts to simplify the test should have been made. Modifications have been devised by Bauer, Tschernogubow, and Noguchi, which, like the regular Wassermann reaction, depend upon the principle of the fixation of complement. A number of other sero-diagnostic methods have also been devised depending upon certain precipitation reactions and having no relation whatever to the principle of complement fixation. They will not be considered in this communication.

Bauer's[17] modification of the Wassermann reaction depends upon the fact that there is normally present in human serum a hemolytic amboceptor for sheep's corpuscles. Bauer, therefore, omits the hemolytic amboceptor (rabbit's serum treated with sheep's corpuscles) in his test, and utilizes the amboceptor present in the patient's serum. The advantage gained by this procedure is that instead of the usual five substances, only four are required for the test. The theoretical objection to the method is that the hemolytic amboceptor in the patient's serum is an unknown and variable quantity. Furthermore, the omission of the amboceptor is, after all, not such a great simplification, for it is in the preparation of the other four substances that the chief difficulties and inconveniences are encountered. The test is further unavailable for use in young infants, as no hemolytic amboceptor is contained in their serum. To supply this deficiency, it is suggested by Bauer to add normal human serum from an adult which will contain the necessary amboceptor. In spite of theoretical objections, Bauer's modification appears to have given good results practically in the hands of Bering.[18] In a series of 123 cases of syphilis tested simultaneously by both methods, the results were identical in all except one case. In this case, which was one of positive syphilis, the Bauer test was positive, while the Wassermann was negative.

The steps in performing the Bauer modification are represented as follows:

Tschernogubow, [19] in his modification, uses a hemolytic amboceptor for *human corpuscles* instead of one for *sheep's* corpuscles. The hemolytic system in this case consists of human corpuscles + hemolytic amboceptor (antihuman) + human complement. In performing the test, a single drop of the patient's blood is used. This is relied upon to supply three of the five substances necessary for the Wassermann reaction, namely, antibodies, complement, and corpuscles. Tschernogubow does not inactivate (*i. e.* destroy complement), considering the complement normally present in the patient's blood available for his test. No guinea pig serum is therefore used. This is an advantage claimed for the test, as well as the fact that a drop only of the patient's blood is used and that no inactivation is necessary.

Tschernogubow's assumption that the complement present in the patient's blood is available for the test has been shown by Noguchi to be correct only when 0.1 c.c. of the serum is present in a tube. In other words, human complement as present in such a small quantity of blood as one drop is, as a rule, too weak to produce any considerable amount of hemolysis of human corpuscles. Noguchi obtained no hemolysis upon adding human complement in amounts as large as 0.2 and 0.3 c.c. to 1 c.c. of a weak suspension of human corpuscles + 2 units of antihuman amboceptor. When, however, guinea pig's serum, even in amounts as small as 0.01 c.c. were added, prompt hemolysis resulted.

The disadvantages in general of using human instead of guinea-pig complement for the test are, according to Noguchi, as follows:

1. By using human complement it is necessary to have ten times as much amboceptor as when guinea-pig complement is used. For this reason the latter is economically preferable.

2. Human complement, like that of the rabbit, is less sensitive to fixation than guinea-pig complement, *i. e.* it does not unite as readily with antigen and antibody.

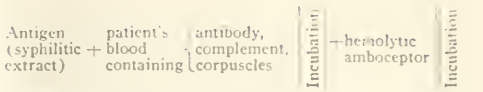
3. The quantity of human complement varies greatly in different sera. If present in excess, the result of the test would always be negative. It is therefore necessary to determine the exact amount of complement present by a preliminary titration, a procedure adding to the difficulty of the test.

4. If human complement is used there is no *direct* way to test the antihemolytic action of the antigen alone, *i. e.* to tell whether inhibition of hemolysis is due to the antigen alone or to the combination of antigen and syphilitic antibody.

5. It is finally impossible by using human complement to test an old specimen of blood, as complement rapidly tends to become inactive. Even the corpuscles begin to disintegrate after a time.

Two of the disadvantages discussed above are mentioned by R. Bauer and Meier[20] as objectionable features in Tschernogubow's test: 1. That human complement varies greatly in amount and 2. That its use necessitates the performance of the test immediately after obtaining the patient's blood. They call attention to the practical point that human corpuscles are not as easy to obtain as sheep's corpuscles.

The step in performing Tschernogubow's modification are as follows:



When Tschernogubow's communication appeared, Noguchi had already completed his antihuman hemolytic system. Noguchi, in his test, employs, as does Tschernogubow, an antihuman amboceptor (*i. e.* a hemolytic amboceptor for human corpuscles), obtained by immunizing rabbits with sheep's corpuscles. Unlike Tschernogubow, he does not depend upon the patient's serum to supply the complement, but uses guinea-pig serum for complement. No inactivation of the patient's serum is necessary as human complement, in the dose used in his test (one capillary drop), is not active against human corpuscles, when 2 units of amboceptor are used. Even in a dosage of 0.1 c.c. it remains without any action at all in the presence of 2 units of amboceptor, and can therefore be entirely disregarded. As indicator, the corpuscles of the patient to be tested or of a normal person are used. The suspension of corpuscles is obtained from the finger or ear and is used in the proportion of one drop to 4 c.c. of physiological salt solution. In this dilution no coagulation of the blood occurs. Noguchi differs from Tschernogubow in using in addition a small amount of serum (containing the antibody). A sufficient amount of serum can be obtained from a half c.c. of blood drawn from the patient's finger or ear. A single drop only from a capillary pipette (which can be easily made in a Bunsen flame) is needed for the test and a second drop for the control. Finally the antigen, complement, and amboceptor have been concentrated, dried, and impregnated in strips of paper, tiny squares of which, representing measured amounts of the impregnated substances are used for each tube. Noguchi has even found it possible to dispense with an incubator by keeping the little tubes in the vest pocket and allowing the body heat to incubate them. In this way he has succeeded in devising a method which is so simple that it can be carried out by any physician without difficulty.

The order of the steps in performing the test is as follows:

1. One drop from a capillary pipette of the serum of the patient to be tested and one drop for the control.

2. One square of paper representing complement or if preferred 0.04 c.c. of fresh guinea pig serum.

3. One c.c. of a suspension of human corpuscles in the proportion of 1 drop of blood to 4 c.c. of physiological salt solution.

4. One square of paper representing antigen, after which the tubes are shaken and incubated in thermostat or vest pocket for a half hour.

5. One square of paper representing the hemolytic amboceptor. The tubes are then incubated again for two hours after which the results are recorded. When examined twenty-four hours later, no change as a rule occurs. The controls are similar to those used in the regular Wassermann reaction.

If the test devised by Noguchi were merely equal in accuracy to the regular Wassermann reaction, its simplicity would mark it as a decided advance in the serum diagnosis of syphilis. That it is actually more delicate and accurate appears from the results obtained thus far by its author. Some rather striking differences in favor of the Noguchi test have been observed among the cases of the writer.

The source of inaccuracy in the Wassermann test according to Noguchi is the presence in the patient's serum of an unknown amount of natural hemolytic amboceptor against sheep's corpuscles, being at times as high as 20 units. The manner in which such as excess of amboceptor may interfere with the test is explained by Noguchi in a critical study to be soon published.

In the first place it is known that increasing doses of amboceptor also increase up to a certain point the activity of the complement. In other words a large amount of amboceptor compensates for a small amount of complement. If, for instance, the complement is not quite fixed in the antigen-antibody combination, the small amount left will not produce complete hemolysis if only 2 units of amboceptor are present. If, however, a large amount of amboceptor is present the effect will be the same as if a larger amount of complement had been present, and complete hemolysis will occur. While one unit of amboceptor + 0.1 c.c. of complement is generally needed to produce complete hemolysis, Noguchi found that if 4, 8, and 20 units were used, hemolysis occurred upon adding 1-3, 1-5, and 1-10 respectively of complement.

In the second place, an excess of amboceptor may bring about dissociation of the complement, *i. e.*, may break up the combination it has formed with the antigen and antibody. If, for instance, a quantity of syphilitic antibody is just sufficient to bind 0.1 c.c. of complement in the presence of 2 units of amboceptor, it will not be able to prevent partial freeing of the complement in the presence of double that amount of amboceptor. For this reason the actual presence of syphilitic antibody may remain unrecognized, as the complement which has been freed brings about hemolysis and gives a negative reaction, where it should have been positive. When the amount of syphilitic antibody is large, this dissociation of the complement cannot take place, *i. e.* a positive reaction cannot be masked.

It is not my intention to discuss in this communication the many phases of the practical application of the Wassermann reaction. Considering, however, that the subject especially in this country is of such recent development it was thought proper to record the results obtained in examining my first cases. All of these cases were adults, about three-fourths being males.

Table I shows the results obtained in 46 cases of clinically positive syphilis, showing active lesions at the time of examination. Of this number, one was a primary lesion of the lip which had existed sixteen days. It gave a strongly positive reaction. Of the 19 cases belonging to the secondary period (first year) all (*i. e.* 100 per cent.) gave positive reactions. If, however, we add 5 cases from table III, which proved to be secondary syphilis, 4 of which were strongly positive and 1 for some unaccountable reason negative, the proportion of positive cases is reduced to 23 out of 24 or 95 per cent. Twenty-six cases of the tertiary type gave 18 posi-

100	Dermatitis herpetiformis	103	Lupus vulgaris	106	Xanthoma tuberosum associated with diabetes

cases in which a perfectly straightforward history of infection could be obtained. Of these cases 4 gave positive, 2 doubtful, and 15 negative reactions, i. e. 19 per cent. only were positive. A glance at

tained in cases (Table IV) where the diagnosis was in doubt and it will perhaps be of interest to describe a few of these cases at some length.

Table III shows a small series of dermatological

TABLE IV—DOUBTFUL CASES.

Case No.	Disease	Mercurial Treatment	Result	Remarks
68	Crusted lesion of lip; syphilis vs. impetigo.	Inunctions, injections and medicine, 3 months	+ +	Later proved to be undoubted syphilis.
69	Syphilis vs. lupus vulgaris.	Medicine, 3 weeks.	—	
70	Doubtful chancre; possible infection 3 months previously	None.	—	Later presented general adenopathy and test became pos've.
71	Peripheral arteritis with symptoms of Raynaud's disease.	Numerous injections.	—	
72	Tubercular syphilide vs. eczema	None.	—	Later proved to be eczema.
73	Previous attacks of iritis; no history of syphilis	Inunctions 2 months	— +	Repeated with same results.
74	Gummata (?); nodules and scars grouped about knee	None.	—	
75	Said to have suffered from syphilis ten years previously	Tablets 1½ years, inunctions 6 weeks..	±	
76	Syphiliphobia; patient's wife had two premature deliveries; any other signs or symptoms pointing to syphilis	None..		
77	Ulceration of nose; history of child born at eight months, no other symptoms.	Medicine, 4 m	— +	Improving under antisphyilitic treatment.
78	Leucoplakia of lip and cheek; chancre (?) 15 years ago	Tablet 1 year, inunctions weeks.		
79	Syphilis (?); septic metritis	None		Impossible to make a second examination.
80	Syphilis vs. epithelioma of tongue, no history of syphilis	None		Clinical evidence strong in favor of epithelioma.
81	Scabies; possible syphilis	None	+ +	
82	Syphilitic vs. traumatic ulcer of lip	None		No effect from antisyphilitic treatment.
83	Macular syphilide vs. drug rash	None	+ +	
84	Amyotrophic lateral sclerosis; gummata (?) of leg	None		Probably not gummata from subsequent course.
85	Miliary papular syphilide vs. scabies.	2 injections of Hg. salicylate		
86	Syphilis vs. epithelioma of glans penis.	2 injections Hg. salicylate	—	
87	Peripheral endarteritis with symptoms of Raynaud's disease; history of syphilis	80 injections		
88	Woman giving history of four children born dead or "mortified"	None		Test to be repeated later
89	Syphilis vs. epithelioma of tongue.	None		
90	Chancre (healing).	None	+	
91	Syphilis of tongue vs. leucoplakia	Medicine 3 weeks	— +	
92	Syphilis vs. erythematous lupus.	Medicine, 3 weeks	+	
93	Syphilophobia.	Injections and medicine	—	
94	Syphilitic rhinitis (?); possible chancre 3 years ago	None	—	
95	Possible syphilis; numerous small tumors of leg; gummata (?) 1 year ago; none since antisyphilitic treatment instituted.	Injection 2 months, medicine 5 months.	—	
96	Said to have had condylomata and circinate eruption of penis 1 month ago; general adenopathy at present	Medicine 1 month.	+ +	
97	Chancre (?) of clitoris; history of 5 miscarriages and 2 children dying early	None		

cases in which syphilis could be excluded (as far as this is ever possible). All gave negative reactions.

Case 69.—Mulattress, 22 years old, presented recently before a medical society as a case of lupus vulgaris serpigenosus. Shows extensive lesions of face, neck, and legs. Family history of tuberculosis. Previous history of suppurating glands. Cutaneous tuberculosis test strongly positive. Histological preparations favors tuberculosis rather than syphilis. As the case was considered by some to be one of syphilis, a Wassermann test was made, with absolutely negative result. Ten injections failed to cure or even improve the disease. Later generally admitted to be lupus.

Case 76.—Case of syphiliphobia. Patient, a physician, had never shown any symptom or sign of syphilis. Two premature deliveries by his wife made him think he had possibly at some time contracted the disease and infected his wife. The patient's peace of mind was restored by a negative Wassermann reaction.

Case 81.—Man, 25, genital sore six months ago followed three months later by a second sore. Examination showed typical lesions of scabies, but with the exception of a slight enlargement of inguinal and occipital glands, no sign of syphilis. The writer doubted the existence of syphilis until the blood was tested and showed a very strong positive Wassermann reaction.

Case 83.—Woman, 42, presented a typical roseola and adenitis. As she had previously taken sajodin, for several weeks, the diagnosis of a drug rash had been made by a colleague of large experience. The Wassermann reaction proved to be strongly positive. In addition the writer found large number of spirochetes, in an ulceration of the vulva, by using the dark field illuminator.

Case 85.—Man, 24, presented as a case of miliary papular syphilide by an eminent dermatologist. Diagnosis doubted and that of scabies made by many, as signs of severe itching were present. The Wassermann reaction was absolutely negative. The later course of the disease showed that it was not syphilis.

Case 86.—Case shown as one of epithelioma of the glans penis, considered, however, by a well-known colleague to be syphilis. Wassermann test negative. No improvement from antisyphilitic treatment. Histological examination showed a prickle cell epithelioma.

While the cases quoted above could be easily multiplied, enough has been said to call attention to the practical value of the Wassermann reaction. That the test is now recognized as a diagnostic procedure of very great value is shown by its well-nigh universal adoption in the hospitals and clinics of Europe.

In conclusion I wish to express my sincere thanks to Dr. Hideyo Noguchi for his generous assistance and advice. The practical work was performed at first by Dr. Noguchi and by myself under his direction until the necessary practice as well as laboratory facilities were obtained. The description of the Noguchi test is from personal communication, as at the time of writing Dr. Noguchi's publications upon the subject have not appeared.

I am also indebted to Dr. Wood McMurtry for the idea of the swinging pendulum.

The greater part of the material was obtained from the dermatological department of the Vanderbilt Clinic, from the service of Dr. George T. Jackson, to whom I wish to express my thanks. Other cases were obtained from the service of my father, Dr. George Henry Fox, at the Skin and Cancer Hospital.

I am also indebted for material to Doctors Whitehouse, Trimble, Clark, Vermilye, Satterlee, Frothingham, and Bradley.

NONGASTRIC MALIGNANT DISEASE AND THE SECRETION OF GASTRIC JUICE.

By LOUIS A. LEVISON, M.D.,

TOLEDO, OHIO.

ATTENDING PHYSICIAN, LUCAS COUNTY HOSPITAL.

It is to Kussmaul's clinic and Reinhard von den Velden in particular that credit is usually given for the discovery that free hydrochloric acid is absent in a large proportion of gastric carcinomata. The date of this communication is 1879. However, there appeared in the *London Medical Gazette*, in 1842, a contribution by an Englishman, Golding Bird, wherein the same fact is brought out. It was his conclusion* "that during the more irritative stage of the disease [gastric cancer] free hydrochloric acid is present in the vomit in considerable quantities, but it gradually diminishes in proportion to the patient's loss of strength; and that the organic acids increase proportionally as free hydrochloric acid diminishes." Not only this, but Bird observed the condition with which this article has to do, namely that free hydrochloric acid was diminished in cancer, not of the stomach (liver). Bird, apparently, did not pursue his observations further than this original contribution and it remained for them to be rediscovered thirty-seven years later by von den Velden, who focused the attention of the medical world on this really important discovery.

Free hydrochloric acid in gastric carcinoma is absent in varying percentage in different series of cases. The percentage of absences in Osler's cases was 89.3, in Boas' cases 77.5, but the percentage is not sufficiently high to warrant this diagnostic sign having more than a secondary value in the diagnosis of gastric cancer, especially in consideration of the many other conditions which can likewise cause an absence or diminution of hydrochloric acid. Immediately on von den Velden's discovery, efforts were made to explain its causation. It was early established that even a small carcinomatous patch localized in the pylorus could cause an absence of acid

*Quoted from "Ewald's "Diseases of the Stomach."

equally as well as a generalized carcinomatous infiltration of the gastric wall with destruction of the glandular apparatus. The view was at first held that the carcinoma produced degenerative changes in the gastric mucosa, starting from the involved focus and spreading over wide areas. This explanation did not satisfy certain conditions, especially the loss of gastric secretion in early cases of small circumscribed tumors. Anatomical investigations having shown that the intact mucosa was involved in neither an atrophic nor a gastritic process, efforts were made to explain the absence of secretion by an alteration of the circulatory fluids, either by some substance produced by the cancer or some other change, possibly nutritional in nature. The occurrence of hydrochloric-acid absence or diminution in the very early stages of carcinoma, before cachexia and emaciation ensued, tended to suggest the cause of the acid deficiency to be a condition preceding rather than following even a moderate tissue involvement.

The hydrochloric acid determinations were at first made with only a few color reagents and indicators. These were rosanilin hydrochlorate, methyl violet, and tropaolin oo, but this list has been extensively widened. Bird's method in his original work was the incineration of the residue after driving off the volatile acids, boiling with nitric acid, and estimating the silver salt. The use of Congo red was introduced in 1886 by Hosslein and Riegel. This red benziolin stain turns blue in the presence of free acids, but the combined albumins or the inorganic bases combined with acids do not respond with a color change. Congo red paper is usually purchased already prepared for use, but this commercial paper is not uniform in its sensitiveness. A 1-1000 Congo red solution is the best concentration and a paper saturated with such a solution should detect hydrochloric acid in a dilution of 0.02 per thousand.

Turning from gastric to nongastric carcinomata, we are impressed by the fact that the attention of the medical profession has not been generally drawn to the changes which occur in hydrochloric acid secretion in cancers, not of the stomach. This change consists in an absence or diminution of acid in a percentage of cases, very similar to the percentage in actual stomach cancers. Despite the apparent neglect of this condition, it was noted in 1842, as mentioned above. Fenwick called attention in 1880 to the occurrence of atrophic processes in the gastric mucosa in carcinoma of remote organs, particularly of the breast, intestine, and uterus. This observation is not strictly analogous, because the occurrence of an atrophic process indicated a local lesion and local lesions are not essential for an absence of acid. Ewald reported in 1886 a case of carcinomatous ulcer of the duodenum in which he found "atrophic degeneration of the gastric glands of the fundus and cardiac portion of the stomach." In this case, too, a local anatomical lesion was present accounting for variations in acidity. Recently, Moore, Alexander, Kelley, and Roaf have reported 34 cases of non-gastric cancers, in which 67.6 per cent. showed an absence of free hydrochloric acid.

My attention was drawn to this interesting condition at that time (1906) and since then, I have been enabled to investigate the gastric acidity in 20 cases of non-gastric malignant disease, 18 carcinomata and 2 sarcomata. These cases were derived from the Lucas County Hospital, the Toledo Medical College Dispensary, and my private practice. Six patients out of the twenty, showed free hydrochloric acid—a percentage of absences of 70. Each of the two sarcomata, one of the leg with metastases in the lung, and the other of the femur and knee, showed an absence of free acid, leaving 12 out of 18 cases of cancer in which free acid was absent (66 per cent.). In these cases, the examinations for free hydrochloric acid were made with fresh Congo red paper and the quantitive examinations were by the Töpfer method. The stomach contents were obtained by aspiration 40 to 60 minutes after an Ewald test breakfast. The Congo red and Töpfer method are fairly reliable for practical clinical purposes, although, of course, not chemically accurate. These cases are tabulated in the accompanying table.

It has been seen that the absence of hydrochloric acid in gastric cancers cannot be satisfactorily explained by local causes. The same difficulty arises in non-gastric cancers and we turn to the circulating fluids for further explanation. The reaction of blood plasma is very near that of distilled water, lying just to the alkaline side of the neutral point. This nearly neutral reaction is maintained by the body with the greatest tenacity, as the animal cells are not able to carry on their various functions in a distinctly acid or alkaline medium, owing to the chemical affinity or tendency to combine between the proteins of the protoplasm and alkalies or acids. This neutral point is being constantly changed and as constantly kept intact. Carbonic acid is being constantly produced in various metabolic functions and would soon render the tissues acid to a poisonous degree, were not this counteracted by an ammonia formation and the presence of organic bases. On the other hand, an excessive alkalinity is neutralized by carbonic acid, organic acids, or the phosphates, carbonates, and proteins which usually hold the balance of power, as they possess the adaptability of acting either as acids or as alkalies.

The reaction of the blood depends on its ionization, a preponderance of free hydroxyl (O H) ions or hydrogen (H) ions determining its nature. Owing to the intolerance of animal cells for concentration in either hydroxyl or hydrogen ionization, the pendulum never swings very far from neutrality, at least normally. Acids or alkalies in the animal economy are irritants in small amounts and as such are speedily excreted by stomach, intestines, or kidneys, but in large amounts the organism succumbs. It is on this account that experimentation with changed reaction of the blood is difficult or even impossible.

The determination of the blood reaction has never been an easy, nor an accurate procedure. The reasons lay in the nature of the blood, its color, its composite character, the varying number of morphological elements, the protein content capable of acting either as weak acids or bases, the contained carbonates and phosphates which can act likewise, and the indicators necessary, of which the list is long but unsatisfactory. The reaction has been uniformly given as alkaline and expressed in terms of sodium hydrate, varying from 150 mg. to 300 mg. for every 100 c.c. of blood. The early method of Landois was too complicated and its modification by von Jaksch, who uses a watch glass containing sodium sulphate and tartaric acid solutions is but little better. Löwy introduced a method in 1894, in which blood is laked with ammonium oxalate, titrated with $\frac{n}{25}$ tartaric acid solution, using as an indicator a lacmoid paper prepared from resorcin and sodium nitrite. Engel modified Löwy's method in 1898 so that a smaller amount of blood would suffice and devised an alkalimeter for the purpose. Dare, using his own special hemoalkalimeter, described in 1903 his spectroscopic method, in which blood is titrated with a dilute tartaric acid solution unto neutralization, at which point the oxyhemoglobin spectrum disappears. Adler described a method in 1907, based on the behavior of rosolic acid to blood serum. Rosolic acid is orange-yellow in the presence of acids, pink in neutral and red in alkaline solutions. According to the recent, careful study of indicators by Edward Salm, rosolic acid and neutral red are two indicators which respond to the slight changes in blood ionization, a change too slight for color reactions from the usual indicator. Adler soaks ash-free filter paper in an alcoholic solution of rosolic acid and then determines the color change in the presence of blood serum. This method determines the reaction only, not the quantitative amount. As a matter of fact, there is no uniform standard of determination of the reaction as this may consist either of an estimation of the amount of acid or base present or an estimation of the preponderance or intensity of acidity or alkalinity as opposed to the neutral point.

In a recent article entitled "A Clinical Method of Hemalkalimetry," Benjamin Moore and Frederick Wilson attempt to solve the problem by a new and unique method. They do not estimate the amount of acids or bases in the blood plasma, nor do they estimate the hydrogen and hydroxyl ionization—the latter a truly difficult procedure. Disregarding the small degree of blood alkalinity, they estimate the ability of the blood proteins and the inorganic phosphates and carbonates to combine with acids or alkalies by means of titration, using phenolphthalein as an indicator. This in reality is a method of determining the ability of the blood to retain its almost neutral point by means of its proteins, phosphates, and carbonates, rather than a determination of the amount of acid or base present.

Moore and Wilson have found in their work that the alkalinity of the inorganic constituents of the plasma in cancer is slightly, but definitely increased; that is, they have an augmented power of neutralizing acids. The bearing of this finding upon the clinical observations brought out in this article, that the acidity of the gastric contents is lessened or absent in non-gastric cancer is important. Such an alkaline change cannot leave the body cells entirely unaltered, as it has been seen how nature abhors a concentration of hydrogen or hydroxyl ions. It is an old observation that the blood alkalinity is increased during digestion, but this is, too, a natural inference, considering the manufacture of hydrochloric acid at this time. If the gastric glands continued to remove hydrochloric acid from the blood in certain cases of cancer, in which the alkalinity is already increased, the cells of the body might be subjected to injurious influences. The above authors do not regard this increased basic reactivity as a result of malignancy because it is found in early cases and also after removal of the growth.

An important subject for investigation is brought up by this question whether the areas, in which primary malignant growths are liable to begin, are not exposed to a higher alkalinity than other regions of the body. It is said that the alkalinity is increased in inflammatory or injured localities and that such increase of alkalinity tends to increased cell growth, especially when continued for long periods of time. Early investigators in this field found an increase of alkalinity in the plasma during old age and the predilection of old individuals and those with chronic inflammatory lesions to malignant disease may have some relationship more than a mere coincidence. This relationship between malignant disease and increased basic reactivity makes practical blood reaction tests very desirable for diagnostic purposes, but it is more than doubtful whether this aid will be generally employed with existing methods.

The work in this connection has been of value from the clinical side in its relation to the hydrochloric-acid secretion in cancer. As free hydorchloric acid is absent in two-thirds of reported non-gastric cancers, its value as a diagnostic sign would be well worth eliciting in cases of obscure visceral disease, where cancer must be excluded. The condition is not of primary importance, but it has a secondary value and, indeed, that is all that can be said of absent hydrochloric acid in the diagnosis of actual gastric carcinomata.

237 Michigan Street.

THE PROBLEM OF EPILEPSY.

By ROBERT H. PORTER, M.D.,

CHICAGO.

This disease can be the better appreciated by the proper recognition of the two most prominent facts in the case: First, the utter hopelessness in the present condition of the epileptic. And, second, the universal prevalence of the disease—one in every five hundred of the population.

The effects of the disease are deplorable enough, and yet the seclusion of the epileptic from all social duties and business life is one of the saddest features, and this no doubt serves to intensify the morbid condition, for the patient is thus debarred from all normal development. In fact, epilepsy is one of the most important social tragedies in the great drama of life, and yet there is more being done for every other class of the afflicted than for the epileptic.

When the epileptic patient comes for advice and treatment there is often a superficial examination, a routine prescription of the bromides, a few suggestions as to diet, and he is directed to call again in a week or two.

From such measures the physician himself ex-

pects little or no benefit, and in this he is not disappointed. For the patient the result is well nigh disastrous, for there has been little or no impression made on either the frequency or the severity of the attacks. In a little while he becomes impatient or discouraged and tries something else, going from one thing to another, trying everything by turns, and nothing long. Some patients select a combination of remedies that seem to give the most benefit, and continue the same indefinitely without any medical supervision, regarding a continuation of the disease as inevitable. The history of the disease is sufficiently well known to need no special attention at the present time.

Epilepsy may be defined as a chronic disease of the brain, accompanied by periodic attacks of a spasmodic character; beginning suddenly, often without any assignable cause, and frequently subsiding as rapidly, either with or without warning and with or without loss of consciousness. And the seizure may be either with or without convulsions.

There may often be a great variety of nervous manifestations either preceding or following the attacks. The old definition of epilepsy as an attack of loss of consciousness with a convulsion is no longer sufficient. In fact, it covers only one form of the disease. As the disease has been more accurately studied in recent years, this term is found to cover a larger field of nervous maladies than formerly. At the present time epilepsy not only applies to what are known as the classical forms of the disease, but it also embraces the various lepsies, such as catalepsy, narcolepsy, hysteroepilepsy, choreoepilepsy, epileptic mania, and also many forms of somnambulism, trance, and a large number of nocturnal seizures, such as night terrors, etc.

Then again there is a large class who occupy the borderland and suffer with attacks of vertigo, confusion, headaches, fainty feelings, and morbid fears that are truly epileptic in character.

And there is another well defined class who suffer with masked epileptic seizures, and these attacks may be either psychic or somatic in character. There may sometimes be shadowy visions, hallucinations or slight delirium, especially at night, with certain antipathies or perversions, often with reference to the patient's own family. And associated with these there may be some petit mal symptoms with choreomania. Then again, at intervals a patient may have erratic motor manifestations of a spasmodic character, and to this class the tramp mania of childhood often belongs, a true procursive epilepsy.

The following is Elbert Hubbard's description of an epileptic attack: "The seizure or spasms of epilepsy is a remedial endeavor on the part of nature to throw off a poison in the system. The primal cause of the immediate explosion is hidden in the secret recesses of infinity—no microscope can find it. But there is always an immediate cause—a pushing of the button—the current goes off with a bang—the vital fluids are shortcircuited, and the burning out of the fuse saves the patient's life. But the tendency is always toward dementia, for the wear and tear on the machinery that races, when the governor is on a strike, is terrific."

The following case presents some interesting features in masked epilepsy:

Recently the writer was called early one morning to see a girl twelve years old, and found that she awoke at five A. M. with severe headache, followed by nausea and vomiting, and there was an urgent desire to evacuate the bladder and rectum, with a slight tendency to diarrhea. She soon went into a deep sleep with stertorous breathing (epileptic coma), which lasted two hours, when she woke up with a feeling of hunger, and, except for a little lassitude, seemed none the worse for the seizure. She had been subject to these attacks for several years, coming on suddenly between four and five A. M., without assignable cause, and subsiding as quickly. There was no loss of consciousness.

The sudden development, the spasmodic character of the attacks, the sleep with peculiar breathing, and hunger on waking, taken in connection with the history of the case were sufficient to make out a case of masked epilepsy, and if anything else was needed it was found in the physical examination of the head of the patient, showing epileptogenic areas in the left parietal and right occipital regions.

There is as much variability in the masked as in the classical forms of the disease, and yet when a proper examination is made a correct diagnosis may always be secured. Some time ago the writer was consulted in one of these cases of masked epilepsy, the patient having frequent spasmodic seizures without loss of consciousness; but as the family doubted the diagnosis of epilepsy the treatment of the case was delayed until after the patient began to have epileptic convulsions.

It is not by any means an unusual thing to find a combination of the three major neuroses developed in a single patient. The insane, epileptic idiot can be found in almost every community, and in any asylum. The common occurrence of epileptic insanity is something more than a mere coincidence. The irritability, with the mental and moral perversions so often seen, even in the early stages of this disease, clearly indicates the tendency to insanity.

Then again, a patient may be seen occupying the borderland between epilepsy and insanity, vibrating first on one side and then on the other, sometimes presenting the obscure problem of masked epilepsy with a psychic equivalent. Not only the frequent development of more than one of the major neuroses in the same patient, but the further fact of their interchangeability through heredity, serve to show the intimate relations that exist between them.

For centuries the epileptic patient has been the subject of the most careful and painstaking study and investigation. And as the result of these studies various theories have been advocated from time to time as to the cause of the disease, but for the purpose of this paper it will not be necessary to recapitulate any of them.

The Predisposition to Epilepsy.—At the present time the causes of epilepsy are divided into two classes: First, the predisposition to the disease, which is regarded as the most important; and second, the exciting causes of the first attack and the subsequent seizures.

It is well recognized at the present time that epilepsy belongs to one of the many forms of degeneracy, and that the condition may vary all the way from a slight deviation from the normal to the epileptic idiot. An examination into some of the causes of degeneration will no doubt aid very greatly in the solution of this very complicated problem. As might be expected, epilepsy is most often found among the defective classes. In all large cities there is a well known class called the hospital population, who, when taken sick, seek the friendly aid of some neighboring hospital

Epilepsy is found to be very prevalent among these people, and from the hospital records of this class of patients epilepsy can be traced running through successive generations. At home they live under unfavorable conditions in overcrowded tenements. The atmosphere is at all times more or less charged with organic and inorganic impurities. The water may often be polluted and the food more or less contaminated or adulterated. There is often an excessive use of tobacco and whiskey, or some of the various drug habits, and there is always more or less excitement, anxiety, or apprehension; conditions that not only serve to produce chronic toxemia, but also to perpetuate the same among this class. Therefore it is not at all surprising that the defective classes should produce epileptic children. But it is also true that a temporary toxemia in the parents may serve to start a degeneration in the offspring that may be both destructive and far reaching in its effects. Thus it can be seen how there may be epileptic children among the well-to-do, for the degenerates are by no means confined to the defective classes. If they were so limited, then the problem could be much more easily handled.

There is another factor that has thus far been neglected or overlooked, and that is the very important question of sleep. It is during the hours of sleep that the most important part of the nutrition and repair of the brain and nervous system takes place. Disturbances of sleep are usually among the early manifestations of the various nervous maladies, and insomnia usually precedes insanity.

Now there is so much life and animation in the cities after dinner at night, that the hours normally needed for sleep are very much reduced. When carefully investigated it is surprising what a large proportion of the city population do not habitually retire before twelve o'clock or later. In every section of the city there are many social functions, receptions, card parties, etc., with refreshments and stimulants of various kinds, each trying to surpass the other; supper after the theater, meetings at the clubs and lodges, as well as the various industrial and political meetings. Bohemia has its various clubs, fraternities, and amusements, as well as Mayfair. In each, often the evening hours are spent in some form of diversion or amusement that may consume more vital energy than the daily duties. Business and other engagements will compel many of these people to get up early; they feel irritable, and if things go wrong are easily worried, and yet they complain and cannot understand why they feel so weary and fatigued all the time. To allay this feeling and to quiet the overstrained brain and nervous system, they begin to use stimulants and narcotics, and while these measures may temporarily relieve the painful excitability, yet in the long run they increase the nervous exhaustion by impairing or perverting the nutrition.

Many never comprehend the injurious effect produced by the habitual use of stimulants and narcotics, and those who do have not the strength of will to resist the insatiable craving, or throttle the demon of thirst. A man addicted to any of the various drug habits, excessive smoking, a vicious or intemperate life, begets enfeebled or degenerate children; and these on account of chronic fatigue and weariness may easily fall victims to narcotics or stimulants, and by such means intensify the degenerate tendency. Conditions such as these may serve either to start or to intensify a predisposition to epilepsy of which so much has been said and written.

While the foregoing is especially applicable to life in any of the large cities, and epilepsy is more often found in the cities than in the country, yet the toxic conditions can also be found in the country, only in a less degree. The frequent pollution of both milk and water in the country is sufficiently well known. And then there are other toxic conditions present, only they are not so manifest, which are at least sufficient to account for the number of cases of epilepsy found in the rural districts. The indications are that as the scientific study of epilepsy progresses it will be found that the primary origin of the disease, or the predisposition to it, is due to antecendent toxicogenic conditions.

While a definite specific germ may be the cause of an acute infectious disease, yet when the patient is examined he is often found to be suffering from a mixed or multiple infection. And so it may prove to be the case in epilepsy. Instead of a single toxemia the disease may be the result of mixed or multiple infections; and the complications so often seen may be started either before or after the disease has taken on an active form. Chronic toxemia sufficient to produce the predisposition to epilepsy may be mental, chemical, or microbic in origin; or more often a combination of these, aided by other unfavorable and morbid conditions.

The influence that a mental impression may have in the formation of the neuropathic diathesis, and by this means be one of the factors in the production of epilepsy, has up to the present time not received the attention that the importance of the subject demands. The detrimental effects which a great grief, a fright, or an emotional disturbance of a depressing character may produce on the life and health of an individual are matters of common observation and of daily occurrence. And it is also equally well known that a mental impression may be transmitted to the offspring as a morbid state. The care, anxiety, and stress of life not only affect the present generation, but produce a detrimental effect on those who follow after.

Worry and the wear and tear of life are but common expressions for the effects of unfavorable mental impressions, and these are well known as prolific sources of many nervous maladies. All of the vital processes, from the digestion of food until the nutritive material is converted into live tissue, are chemical in character. Now a distressing mental impression may instantly change the digestive or nutritive secretions from a benign to a toxic character; and no doubt all the other and more obscure vital processes are equally sensitive.

Not only is this the case with us, but the statistics of all highly organized countries show a high rate in the increase of nervous maladies, due to the great strain and stress of modern civilization. The great battle of life is fought now, not by thews and sinews, but by the brain, and he is maimed indeed who is crippled in the brain.

A chemical disturbance of digestion and assimilation, or some of the more obscure vital processes may sometimes serve so to impair the nutrition of the brain structures as to start an epilepsy. This is especially true when associated with depraved habits, intemperance, and excesses of various kinds. The habitual use of stimulants and narcotics, with the various drug habits, have the effect of impairing the vitality and stability of the brain structures.

Inebriety is at the present time recognized as such a potent factor in the production of epilepsy, both in the individual and his descendents, that there is a strong effort being made to put them into a separate class, known as alcoholic epileptics. It is said by some competent authorities that there has been a large increase in this class, during the last few years, especially among those who are addicted to fancy drinks, where the impure spirits or wines can be masked by the highly pungent flavorings.

The excessive use of tobacco, in the experience of the writer, must also be regarded as an element in the production of the neuropathic diatheses. Some of the worst cases of both epilepsy and insanity can be directly traced to the immoderate use of tobacco. The various drug habits also have an important bearing on the same great question.

Max Nordeau has well said that "a race which is regularly addicted, even without excess, to narcotics and stimulants in any form begets degenerate descendants who, if they remain exposed to the same influence, rapidly descend to the lowest degrees of degeneracy, to idiocy, epilepsy, etc."

Then again, the bacteriologists are continually warning us of the great number and variety of the microbes to which we are at all times exposed, some of them benign and others toxic. The atmosphere may be charged with impurities by the various germs which it contains, the water may be polluted, or the food may be contaminated by them. When they are once deposited in the system, they may remain latent indefinitely, until the conditions prove favorable for their development. And some recent investigations show that they may even be transmitted to the offspring, and no doubt some diseases are transmitted in this manner.

The life, habits, and environment of the individual may serve either to attenuate or to intensify the effects of the toxic germs; and then again the vital state may also serve so to modify some of the benign germs as to convert them into toxic ones. In whatever manner the germs may enter the body and, later on, in whatever way they may excite disease of the same, it is only by impairing, either directly or indirectly, the nutrition of the cerebral cells that they may become an essential factor in the primary production of epilepsy.

The complications encountered in the life history of the disease, especially during the period of latency, will sufficiently account not only for the diversity of development in different patients, but also for the variability of the symptoms in the same patient.

Owing to the character of the symptoms, epilepsy has been regarded as a chronic disease of the brain from the time of the earliest writing on the subject. All the facts in the case indicate that the influence of the toxicogenic conditions has continued for a long time and has been of sufficient force in some cases to modify so profoundly the nutrition of the brain and nervous system as often to produce an arrest of development in certain lines as well as perverted activity in others before the disease assumes an active form. These marked deviations from the normal give the patient and his friends a sufficient warning of the approach of the great tragedy.

Chronic toxemia produces a chemical nutritive change in the conditions of the cortical cells of the brain, and when these cortical cells with perverted nutrition are unduly stimulated by congestion, there is a perverted sensorimotor and sensoripsychic functional activity of the brain. And this incoordination of the brain functions is the essential feature in every epileptic seizure, whether mild or severe. Nature, in an effort to correct this impairment of nutrition in the brain structures by an increased blood supply, produces what may be termed passive congestion of the affected regions, so that the epileptic all the time has too much blood in the head. This impairment of nutrition, with the increased blood supply to the impaired tissues, makes them very sensitive to disturbances of the circulation from causes either within or without the brain.

The location and extent of the congestion of the brain that is associated with the recurring attacks, can generally be determined by a careful physical examination of the head. Tenderness and pain on pressure are indications of disease here, just as in any other part of the body, and their location may serve to show the character of the symptoms and many of the complications associated with the disease.

Occipital tenderness on pressure can be found in nearly all cases of epilepsy, and next in order of frequency are the parietal regions, on either one or both sides. In a few cases, there is marked tenderness more or less all over the head.

In the opinion of the writer, chronic congestion of the affected regions of the brain is always associated with epilepsy. Acute congestion is the exciting cause of the recurring attacks, and these sensitive regions indicate the diseased areas with local congestion. It is well known at the present time that the different attacks of epilepsy are only the symptoms indicating this diseased condition of the brain, and that the seizures will vary according to the location and character of the morbid conditions present.

Heredity.—It is well known that heredity is an important factor in the production of epilepsy. The various writers on the subject differ somewhat in the percentage of the cases that they attribute to this cause. And then there are many cases with a morbid bias, that for various reasons cannot be accurately traced. The alienists say that it requires two generations to produce insanity, and this is no doubt equally true of epilepsy.

Some time since a professor of one of our universities who is an authority on animal industry said that "the markings and colors of a herd of cattle could often be traced back for a period of three or four hundred years." If the colors, then certainly other traits were also transmitted. A few days ago, in an interview, a well known florist, who is an expert on the cultivation of carnations, said that "some of his best varieties, in the highest state of cultivation, would sometimes produce a plant that would revert back to the original type of three or four hundred years ago."

Then if plants and animals carry the influence of heredity for three or four hundred years, the present type of man is made up of the normal and morbid conditions of the civilzation that has preceded. This is true to such an extent that I have long since ceased to ask any questions about the heredity of the patients who come to consult me for epilepsy. I simply regard the patient as unfortunate in the chemical compounds that go to make up the nutrition of his brain cells.

That heredity plays an important part in the production of epilepsy is certainly true, and this can be better understood when it is remembered that in the absence of neurophatic progenitors, the parents may

suffer from a temporary toxemia at a critical period, and in this way transmit a neurophatic diathesis that may develop into epilepsy. The interchangeability of the various neuroses through procreation is another prolific source of epilepsy. The direct transmission of epilepsy from parent to child is seldom seen among the well-to-do. In fact, under favorable conditions, the disease is eliminated through propagation of the race. If it were not so, we would all have been degenerates and epileptics long before this time.

The elimination of disease through procreation is nature's great provision against degeneracy. Now if nature usually eliminates the disease in propagating the race, then science certainly ought to arrest and eliminate it from the individual, for nature is all the time making an effort to restore the normal.

The hospital statistics show a large percentage of the direct transmission of epilepsy from parent to child; and yet, under the circumstances, this is nothing more than what ought to be expected. The post-mortem examinations made from the hospital population show degenerative brain changes similar to those found in many cases of epilepsy, and this fact readily accounts for the frequent transmission of epilepsy in this class.

Then poverty and ignorance, with vicious and depraved habits, are often fruitful sources of the disease.

Exciting Causes.—Now in regard to the exciting causes of epilepsy, the conditions that may serve to start the first convulsion. While they may be important as the beginning of a great tragedy, yet they are of minor consideration in comparison with those that serve to produce what is called the latent tendency, the predisposition to the disease. And this predisposition may be either inherited or acquired. The times of the first and second dentition and puberty are the most critical periods for the development of epilepsy. At each of these periods many cases begin without any assignable cause.

Great emotional disturbances, such as fright, excitement, worry, care, or anxiety, loss of sleep, overstudy, a great grief, etc., are among the most frequent exciting causes of the first attack. In fact, when a definite cause is given as the beginning of the disease, more than one-third is attributed to some emotional disturbance. Gastrointestinal disorders occupy an important place as exciting causes of the first attack; such are acute indigestion, worms, intestinal toxemia, and constipation. Then the infectious fevers, typhoid, diphtheria, measles, and other infantile maladies are among the well known exciting causes. And many cases are attributed to falls and injuries of various kinds.

Then there are many miscellaneous conditions that are occasionally given as the cause of exciting the first attack, but it will not be necessary here to go into sufficient detail even to mention them. Sometimes certain conditions may be regarded as danger signals in this disease. And among these may be mentioned the various nocturnal seizures, such as vivid and frightful dreams, crying out in sleep, night terrors, etc. These often develop into nocturnal convulsions. And then habitual nosebleed in children or about puberty, when arrested, is often followed by epilepsy.

A theory that is being discussed at the present time, that regards acute toxemia as the cause of the recurring attacks of epilepsy, takes a too superficial view of a very great problem. That there is often acute toxemia and autoinfection in epilepsy is no doubt true, but the writer does not believe they occupy the place of controlling factors in recurring attacks.

Some recent investigations show that the blood of an epileptic is in a toxic condition after an attack, and that the toxic effects of the urine are very much increased after a seizure. A further investigation of the subject may demonstrate that these toxic conditions coming after the attacks will be properly classified among the effects of the seizures, instead of the causes.

It is a well known fact that the post-mortem examination of the brain of a chronic epileptic shows great dilatation of the blood-vessels with distention of the perivascular sheaths, the effects of chronic congestion. With this condition of dilatation and chronic congestion, it would be very easy to excite acute congestion of the brain. A careful clinical study of the epileptic patient shows that close application with great mental effort, excitement, the use of stimulants, and everything that increases the brain circulation causes an increase in both the frequency and severity of the epileptic seizures; while a quiet life with brain and vascular sedatives will arrest the attacks in many cases and prove beneficial in others. And in addition to this, whenever an epileptic dies in convulsions the brain shows the effects of acute congestion. This corresponds with the opinion handed down by Hippocrates, and confirmed by competent authorities ever since, that congestion of the brain is the cause of the recurring attacks of epilepsy.

Dr. Van Gieson, in studying the interparoxysmal periods of epilepsy, has discovered a fine tremor, imperceptible to palpation, but the tracings of which can be easily perceived by means of accurate mechanical appliances. This tremor sometimes begins two or three days before, and gradually increases in intensity up to the epileptic seizure. He has often been able to predict with accuracy a return of the convulsions from the tracings of the tremor. No doubt this tremor is produced by the acute congestion of the brain that precedes and causes the attack. Often the friends of a patient can see the premonition of an approaching attack by the flushing of the face and head with the increased color that precedes it. Many patients have a jerking and twitching of the limbs while sleeping, somewhat similar to Van Gieson's tremor, only more pronounced, a true nocturnal chorea. This nocturnal chorea is always worse just before and during the time of convulsions. These flushings and the increased nocturnal chorea are the effects of the acute congestion of the brain.

Clinical experience has many times demonstrated the fact that remedial measures that will control the nocturnal chorea, restrain the reddening of the face and head, and check the congestion of the brain, will at the same time arrest and control the threatened epileptic convulsions. The demand of the impaired cells for more and better nourishment cause an increased blood supply. Then it must be remembered that deficient nutrition is the ordinary cause of local congestion; and that the impaired nutrition of the rain cells in epilepsy supplies the efficient cause for this congestion of the brain. Owing to the exhaustion of the brain cells from impaired or perverted nutrition they are oversensitive and easily excited by this slight congestion into perverted action, and herein lies the essential feature of every epileptic seizure; congestion of the

affected regions of the brain, brain cells with perverted nutrition unduly stimulated, causing perverted functional activity.

The dreadful convulsions are but the outward manifestations of the tornadoes that are sweeping over the brain centers within. If these are the external expressions, one can easily imagine what the internal commotion must be.

A paper will appear soon giving the medical management and showing the beneficial effects of the practical application of the foregoing theories.

ACUTE POSTOPERATIVE JAUNDICE.

By CHARLES GREENE CUMSTON, M.D.,

BOSTON, MASS.

Many theories have been put forward to explain the pathological physiology of icterus, but I shall be brief in regard to them, although there are certain acquired facts which I should like to consider rapidly. Let us take the most simple case, that is to say retention jaundice. If in the dog the choledochus is tied, in about two hours the blood and lymph coming from the liver will be tinted yellow. There is evidently here an intrahepatic absorption of the bile, thus proving a law established long ago by Bernard, that the glands are or may become organs of absorption quite as much as of secretion. In cases of icterus by retention in order that there may be a true or bilipheic jaundice, two conditions must be realized, namely, a preservation or even an increase in the biligenic function of the hepatic cell, and secondly, an inverted secretory current of the bile with diffusion of the bile by the suprahepatic veins and lymphatics, so that it no longer passes by the natural tract.

It not infrequently occurs that in subjects presenting jaundice of a subicteric condition, the urine appears devoid of biliary pigment. Nitrous nitric acid when poured along the sides of a test-tube will give rise to a brown color but Gmelin's reaction does not take place. It was to explain conditions of this type that Gubler gave forth his ingenious theory of hemapheic jaundice. The hemoglobin arising from the destruction of the red cells becomes transformed into bile-pigment and is eliminated by the bile. Under the influence of some morbid process a too rapid destruction of the red cells takes place, and, the liver becoming impotent to transform the hemoglobin set at liberty into biliphein, the coloring matter of the blood accumulates in the serum, at the same time undergoing various changes in the circulatory current. It is to these pathological pigments which are derived from an incompletely elaborated hemoglobin, that the name of hemaphein has been applied, while the term of hemapheism is given to an accumulation in the blood serum of the above mentioned product, this condition also arising when the liver is suddenly and severely attacked in its secretory activity.

Many serious objections may be made to this theory, the first of which is that hemaphein has never been isolated from the blood-serum or the urine and probably does not exist. In samples of the so-called hemapheic urine, Tissier has shown that certain specimens if diluted, would give rise to Gmelin's reaction, and consequently these urines must contain abnormal pigments besides more complex products, such as modified pigments and urobilin and its chromogenous pigment.

Urobilin is a derivative of bilirubin, the former being derived from hemoglobin. Hayem's hepatic theory of urobilinuria explains clinically a number of cases. Urobilin is a pigment coming from a diseased liver, a product of hepatic insufficiency, and there is a constant relationship between an intense and persistent urobilinuria and atrophic or degenerative lesions of the hepatic cell. It is in the liver and not in the blood-serum that the transformation of hemoglobin into urobilin takes place, because in cases of this type the bile in the gall-bladder contains post mortem a more or less considerable quantity of urobilin, occasionally at the exclusion of every other pigment. Thus we have a diseased hepatic cell, a defective evolution of the blood-pigment which transforms into urobilin in the liver, absorption, resulting in urobilinemia, the outcome being the elimination of the pigment in the form of urobilinuria.

The reddish brown pigment, first isolated by Winter, is the most important of these as yet badly understood pigments. It is an intermediary between urobilin and bilirubin, arising from the latter by a process of reduction. Nitrous acid produces a dark brown color of the urine when the latter contains this pigment.

At the present time our knowledge of these modified pigments is most incomplete, particularly in the case of the reddish brown pigment, and nevertheless, in certain cases, the latter seems to impart a yellowish tinge to the integuments.

The classification of jaundice into four groups, as has been made by Hayem and Tissier, shows the possible multiplicity of the stages gone through in a case of icterus, and one not infrequently will find the bilipheic, hemapheic, and urobilic phases succeeding one another.

In reality, however, there is no such process as urobilic jaundice; there is only a jaundice with urobilinuria, when there is icterus with urobilic urine; the blood-serum not only contains urobilin but also normal or modified bile pigments as well.

The classification referred to is as follows: (1) *Bilipheic jaundice,* which from the commencement remains as such, with or without urobilinuria. (2) *Gubler's hemapheic jaundice,* in which the blood-serum contains biliary pigment in quite large amounts and traces of urobilin, while the urine contains urobilin associated with changed bile pigments. (3) Cases of slight jaundice where the urine only contains urobilin, while the blood-serum contains both urobilin and bile pigments. (4) Jaundice in which the blood-serum and urine contain only urobilin.

Now the question is: In other cases can there be a jaundice of hematic origin without any intrahepatic absorption of the pigment products; in other words, is there such a process as hematolytic jaundice? In reply to this I would quote Chauffard. "These forms of toxic icterus, hematogenic in appearance, are so in reality and it may be said that jaundice is the morbid function of the hepatic cell, just as biligenia is its normal function." And, consequently, the conclusion may be drawn that jaundice is merely symptomatic of intrahepatic absorption of normal or modified bile pigment. This absorption depends on an inverted secretory current of the bile, while the pressure becoming increased more in the biliary tract than in the lymphatics, they are eliminated by the blood. In all cases where there is an evident mechanical obstruction, retention of bile is manifest, but in order to explain the

experimental toxic jaundice, as well as the several types met with in man, the very special appearance of the bile as pointed out by Stadelmann should be considered. The bile is thick and being overcharged with pigment cannot easily make its way along the choledochus; it stagnates, producing a hypertension in the biliary tract and finally becomes absorbed. The similarity noted in experiments between the changes in the bile and the occurrence of jaundice, would seem to prove the correctness of this theory.

In the cases that are reported at the end of this paper where jaundice occurred after operation, it is to be noted that none of the interferences were on either the liver or the biliary tract. As the title of the paper indicates, I shall limit my remarks to cases of postoperative jaundice arising after operations on other organs. I have also considered it proper to eliminate all operative interferences on the appendix because it is well known that when jaundice does occur in appendicitis, the latter process is in itself quite capable of producing the former. I believe from my own experience that a subicteric tinge of the skin and conjunctiva is not of uncommon occurrence following removal of the appendix, and in several instances I have found it present before operation was undertaken.

Referring now to the subject proper of the paper, it may be said that some writers have thought that postoperative jaundice was due to the absorption of a large quantity of blood, such as operative or traumatic hematoma, likewise a large extravasation of blood. The explanation given for these cases is that there occurs a hematolysis, and if a blood examination is made one will find that a very large amount of hemoglobin is dissolved in the blood-serum. No oxyhemoglobin will be found in the urine, because the renal filter will not allow this pigment to pass through it. The kidney reduces the homoglobin into bodies of the same series and less oxydized, which will then pass into the urine in the form of urochrome, uroseine, urohematic pigments, etc. Speaking of the jaundice of newly born infants, Leuret says that at the time the integuments are yellow, the blood-serum will be found to have an orange color, and by the spectroscope the spectrum of oxyhemoglobin will still be found. This is, however, of short duration and the yellow color will soon become marked and the color of the blood-serum will be such that one might be led to believe that bile pigments are present therein. However, Gmelin's reaction will conclusively show that there is no bilirubin, so that one is obliged to admit that the body present is composed of the yellow pigments of the blood. Some writers believe that these are modified bile pigments, but the question is how they get there and what part the bile may play in the blood changes.

It would seem preferable to admit that the hemoglobin gives rise to yellow pigments when, by contact with the tissues, it becomes reduced. The yellow pigments are as yet undetermined, but are not bilirubin; they impregnate the tissues and give rise to the jaundice. At this stage of the jaundice, the urine is highly colored and will be found to contain pigments derived from hemoglobin, but not so highly oxydized as the former. The organism quickly gets rid of these foreign bodies, the urine becomes normal although the integuments remain yellow on account of the impregnation of the deep layers of the skin.

This theory which has been emitted by Leuret to explain the jaundice of the newborn, is, in the case we are considering, susceptible to very serious objections. In the first place, I would point out that the case of slight hematoma recorded by Santucci is the only instance of acute icterus following hematoma that I know of, and it would seem that if the above theory were correct, acute jaundice should be frequently observed during the period of resolution in cases of large collections of blood following fractures and severe contusions. In the above mentioned case it should be pointed out that the jaundice occurred a day or two after the operation, before the hematoma was cleaned out, consequently its appearance was too rapid for blood absorption to have been the cause. It might have been more logical to consider the hematoma as secondary to the jaundice, as under these circumstances the blood would have less tendency to coagulate and consequently the small vessels which were not ligated could have bled.

Some writers have thought that acute postoperative jaundice was due to a reflex spasm of the gall-bladder of peritoneal origin. It is certain that such an explanation has much in its favor. The parietal peritoneum is extremely sensitive to pain, as all those who have performed abdominal operations with local anesthesia are aware, and it cannot be denied that irritation of the serosa might easily provoke spasm when during the operation the parietal peritoneum is handled.

In reference to this subject, Santucci has recorded the case of an elderly man, operated on for inguinal hernia. During the tying off of the sac the patient experienced a very sharp pain, and in the evening there was a tendency to vomiting, while the next day the patient several times vomited a liquid containing biliary products. It was not believed that this was due to paralysis of the intestine because the latter had not been manipulated during operation, and also because the bowels had moved and there was no distention. As the vomiting soon stopped without any treatment it was considered reflex.

Since the writings of Lennander we know that the visceral peritoneum, including that of the mesentery, has no feeling for heat or cold, and the same applies to the mucosa of the intestine and gall-bladder. On the other hand, the parietal peritoneum is particularly sensitive to contact, but it does not react to heat. This sensitiveness is due to the lumbar and sacral nerves which pass in the subserous tissue. Now, since pain is done away with by general narcosis, consequently the reflex must start from the nervous filaments of the parietal peritoneum, as pain is out of the question. At any rate it may be questioned why this hypothetical spasm of the biliary ducts does not take place oftener, when one considers the enormous number of abdominal operations performed.

If acute postoperative jaundice is to be imputed to spasm of the biliary tract, resulting from a peritoneal reflex, it should arise very frequently in abdominal operations done under local anesthesia, much more frequently than those who are submitted to the influence of an anesthesic. Then, again, how can one explain the occurrence of this complication after circumcision or resection of the jaw? A spasm of the biliary ducts produced by a simple irritation of the parietal peritoneum cannot be, in the majority of cases, a necessary factor in the production of acute postoperative jaundice, and must merely be considered as a secondary cause.

A certain number of writers have recorded cases of serious jaundice occurring after operations done under chloroform. Wells, Ochsner and Bayard Holmes believe that chloroform is a cause, while W. W. Keen is inclined to attribute this jaundice to an infection or to the action of the anesthetic. Bandler, Cohn, Marten, and Bastianelli also incriminate chloroform. Ballin has collected several cases of serious postoperative jaundice. One or two days after the operation a slight icterus is noted, accompanied by vomiting which may be bloody; the icterus persists, while fever, albuminuria, vomiting, and delirium or coma occur. Death is the usual outcome in these serious cases because it has been shown that 90 per cent. of the patients die. Many other writers, the list of whose names would be too long to mention, consider these serious cases as resulting from an intoxication by the anesthetic, especially chloroform. Lindh has examined 15,052 narcoses and found only ten cases of post-operative jaundice. It occurred nine times out of 11,284 anesthesias with chloroform, in other words, 0.079 per cent.; with ether-chloroform narcosis there was one instance out of 2,122 anesthesias, or 0.047 per cent.; in 1,297 ether narcoses none occurred; while out of 362 narcoses with ethyl bromide or ethyl bromide and chloroform, there were five cases. Out of 40,000 narcoses at the Kharkov Hospital, Grube did not observe a single instance, while in 1902, Delbet stated that the combination of ethyl bromide and chloroform was particularly toxic for the hepatic cell. Years ago I was in the habit of having my patients anesthetized with the above mentioned combination and of over 200 cases I never met with this complication. Richelot also states that he has never met with it under these circumstances.

I would here like briefly to refer to the experiments of Nothnagel on fatty degeneration produced by intoxication from ether and chloroform. In speaking of ether he relates a series of experiments. In the first, a rabbit was kept under the influence of ether for three hours, although narcosis was not complete. After the animal had recovered, the urine drawn from the bladder gave a very marked reaction of bile-pigment. Another rabbit was kept under an incomplete narcosis for two hours and then suddenly died. The urine obtained from the bladder gave a bile-pigment reaction, while microscopical examination of the liver showed that it was filled with drops of fat. In another experiment ether was directly injected into the stomach of a rabbit, and in this case the hepatic cells were completely loaded with drops of fat, so much so that their nucleus was hidden. Five experiments were carried out with chloroform, either injected into the stomach or subcutaneously. One rabbit received an injection of 4 cc. in the stomach and died about seven hours later. The urine did not show any reaction of bile but the liver was white in color and at certain spots the acini were cloudy and opaque. The cells were filled with rather large, fat globules.

We may consequently conclude that very often the urine gives a positive reaction of bile-pigment and that in all the experiments where death resulted to the animals a fatty degeneration of the various viscera was found, more intense when ether or chloroform were directly introduced into the stomach. The heart and liver were particularly involved and it would seem from this that both these anesthetics are toxic for the liver. Although ether narcosis would appear less prone to produce acute postoperative icterus, it will be seen that both my patients had ether and nothing else, and that in both, as the operations were short, the amount of ether given was small. It may be, however, that the rapidity with which the blood cells are destroyed during etherization that the usual appearance of polycholia occurring at the same time with the rapid liberation of hemoglobin which is absorbed by the liver, may considerably increase the quantity of pigment. There is one fact, however, which seems positive and that is that ether is far less toxic for the liver than chloroform, because occasionally one finds very small traces of urobilin or bile-pigment in urine after narcosis with chloroform, although the patients may not present jaundice. Hofmeier has stated that the use of chloroform during labor favors the occurrence of true jaundice in the infant, while on the other hand Vidal, Zeller, and Kappeler in numerous experiments both on man and animals were never able to obtain a trace of pigment, while urobilin was met with in only two instances by Vidal. From this is would seem that the toxic action of chloroform and ether cannot be denied as a cause of acute postoperative jaundice, but usually this toxic influence makes itself evident when the hepatic cell is in a pathological condition, such as arises from the use of alcohol or in lead poisoning. It should also not be forgotten that certain subjects possess a particular susceptibility to intoxications, especially of the liver.

Santucci has examined the direct action of chloroform on the mucosa of the digestive tract, and he mentions instances of chloroform narcosis where the patients had only inhaled a very small amount of the drug, who during the days following presented an aversion for food, nausea and coated tongue. He states, however, that the preoperative care of the intestinal tract had been carefully gone through with. However, it would seem that the serious form of acute post-operative jaundice is almost always due to the toxic action of chloroform on the hepatic cell, whose normal condition is below par.

I would now briefly refer to the question of emotion as a factor of acute postoperative jaundice. A severe moral shock will often disturb the functions of the biliary system so that jaundice occurs, and no matter how this icterus may be explained, whether by spasm of the choledochus or by a centrifugal reflex, it is nevertheless practically certain that instances of emotional jaundice do occur. The jaundice occurs without elevation of the temperature and no disturbance in the general condition other than that arising from absorption of the bile and is of short duration.

It is quite true that instances of this form of jaundice have been noted in cases where patients have requested operation, and it is possible that the mental suffering was the cause, but on the other hand this type of jaundice is exceedingly rare, and patients as a rule do not present it because their apprehension of the operation does not manifest its effect until a day or two after the interference has taken place.

The existence of acute postoperative jaundice cannot be denied merely from the fact that few cases are encountered, and in conclusion I would say that it is probably due to several causes. There may be occasionally a spasm of the biliary tract produced by manipulation of the parietal peritoneum, while in other cases it is due to an exo-

tional reflex. Icterus gravis is probably caused by the toxic action of the anesthetic, particularly chloroform, which attacks the hepatic cell already pathologically altered, and for this reason, before undertaking any surgical interference, the surgeon should look into the functional condition of the liver of his patients and resort to surgery only in cases of extreme urgency when the liver gives evidence of disease.

Case I.—Male, thirty-seven years of age, slightly alcoholic, presenting a left inguinal hernia. At the operation the sac contained only omentum, a portion of which was resected. The operation was easy and rapid. Ether narcosis. On the next day the patient complained of pain in the region of the liver and presented a mild degree of jaundice. He was placed on a milk diet, the bowels were freely opened with salines and at the end of nine days he had completely recovered. The wound healed by first intention so that the cutaneous sutures could be removed on the fifth day and therefore the case cannot be considered one of a mild infection, because the temperature did not rise and the pulse remained at from 72 to 80 throughout.

Case II.—Female, forty-nine years of age, mother of three children, had complained of pain in the right hypochondrium which occasionally occurred in intense paroxysms. For the last year she has noticed a tumor on the right which appeared to be movable. There was no disturbance of the micturition. On examination nothing could be found abnormal in the thorax. By palpation, a tumor, the size of a grapefruit, could be found under the right costal border its surface was smooth, somewhat painful on pressure and it could be moved downward almost to the right iliac fossa. Diagnosis: Ren mobilis dexter. Under ether narcosis nephropexy was performed according to Ochsner's technique. Upon the following day symptoms of peritoneal reaction arose, followed by vomiting and afterwards by a very intense jaundice. A positive reaction of bile-pigment was found in the urine. By the end of a week the jaundice had disappeared and she recovered without any further complications. In this case also the operation was of short duration, twenty-five minutes, and entirely extraperitoneal. The wound healed perfectly, presenting absolutely no reaction and the skin sutures were removed on the sixth day. Consequently both infection and peritoneal irritation must be eliminated as the cause of the jaundice and the anesthetic incriminated.

871 Beacon Street.

A NOTE ON POISONING BY EGG.*

By D. J. M. MILLER, M.D.,

ATLANTIC CITY, N. J.

VISITING PHYSICIAN TO THE CHILDREN'S HOSPITAL OF PHILADELPHIA.

My attention was first called to poisoning by eggs some eleven years ago, when the case forming the basis of this paper came under my observation. Since then I have encountered several cases, and, from time to time, various allusions to the subject, in the course of my reading. This material I bring together in the brief note which I present this evening.

My patient, now a girl of eleven years, first showed her inability to take eggs, when, at the age of twelve months, the raw yolk of an egg was added to the bottle (a not uncommon practice with me at this age). This was followed in about one and one-half hours by pallor, nausea, cyanosis, contracted pupils, severe vomiting, prostration, muscular weakness, and weakened pulse and cardiac action. These symptoms lasted about five or six hours, when the vomiting ceased, and the child slowly rallied. Diarrhea then supervened, and slight fever, forty-eight hours elapsing before the infant had regained its usual health. A few weeks later a similar, but less severe, train of symptoms followed the admixture of the whole egg with the child's milk. The white alone of one egg was then added to the bottle, but caused no disturbance. On another occasion, I gave the yolk alone, but slightly cooked, and again the child was made ill; although again to a less degree than at first. This peculiarity, or idiosyncrasy, if you choose so to call it, was found to exist whether city or store eggs, or when eggs, which I had every reason to believe were fairly fresh, were eaten by the patient. After the fifth year attempts were made to educate the child's digestive organs to tolerate and convert egg-yolk, by feeding it to the child in small quantities at a time—to render the child immune, as it were. By this means the idiosyncrasy, or susceptibility, was gradually overcome, so that now (at 11 years) the little girl can eat eggs, both yolk and white, without difficulty, unless continued too long, or in too great quantity, when the familiar train of symptoms, which we designate as biliousness, will supervene.

Idiosyncrasy as regards eggs is not so very uncommon. People constantly assert that eggs make them bilious, and while in some this is often imaginary, in others the inability actually exists. This is notably true of infants and young children. Anyone who has had much experience in the feeding of these little patients must have observed that not only many infants and young children digest eggs with difficulty, especially when first eaten, but also that many more are made ill if this particular food is partaken of too freely, or, in the case of older children, if the egg diet is kept up too continuously. This inability of young children to digest eggs is probably in line with the well-recognized fact that the infant's stomach, or digestive juices, must be taught to digest most dietary articles other than the maternal milk. Cows' milk, for instance, is a veritable poison to some infants, while many a newly-born requires some practice and education before it can thoroughly digest even its own mother's milk.

Instances of egg poisoning appear from time to time in periodical literature, and the subject is referred to in some, but, by no means all, works on dietetics. Thus two cases are reported in the *Journal of the American Medical Association* for the current year. Mr. Jonathan Hutchinson, in his lectures on "The Pedigree of Disease" (London, 1884) refers to several cases of this nature, in some of which the symptoms were so violent as to excite suspicion that poison had been given. In the *British Medical Journal* for March 11, 1899, may be found the interesting history of a case, in which the very smallest quantity of egg caused the most violent symptoms, resembling those of an irritant poison. In this patient even the placing of a small portion of egg-albumin on the skin was followed by an abundant urticarial eruption. In a case reported by Anderson (*Journal of the American*

*Read at a meeting of the Atlantic County Medical Society, December 18, 1908.

Medical Association, March 7, 1908) one-half teaspoonful of froth of egg-water produced, at once, in a boy of thirty months, vomiting, cyanosis, rapid pulse and coma; and, on another occasion, a coddled egg caused the same symptoms, and, in addition, a profuse urticaria. In the issue, two weeks later, of the same journal (March 21, 1908), Vaughan writes of a young man of nineteen years, in whom gastrointestinal symptoms, with urticaria and a scarlatinous erythema, were induced by eggs. This patient could not tolerate eggs in any form or quantity; even a cake made without egg would produce symptoms, if the knife used in cutting it had previously cut a cake containing eggs. Clemens (*Medical News,* April 16, 1904) has also recorded the violent poisoning of a child, on four different occasions, from albumin water.

Individual susceptibility, as regards eggs, is extremely variable; in some persons eggs always act as poisons, while in others the toxic influence may be marked at one time, and at another much diminished or entirely wanting, especially when the subject is in sound physical condition. The susceptibility may be observed in eggs of every degree of freshness, and in some cases only with the eggs of certain birds (J. Hutchinson). Changes in eggs may also be brought about by methods of cooking; for while some persons manifest their susceptibility only when the egg is raw, others are poisoned when it is cooked or prepared in some unusual and unaccustomed manner.

In my patient the poisonous symptoms were produced by the yolk, but in most of the reported cases the white of the egg appears to have been the offending element. The symptoms of egg poisoning differ greatly in degree; in some cases only nausea, vomiting, and headache occur; in others the most violent symptoms, suggestive of irritant poisoning, are observed; again, in certain individuals eggs, especially if their use is long continued, give rise to the symptom-group which we call biliousness which, after all, is but a form of autointoxication, due, possibly, to the presence of some alkaloid in the blood. As the symptoms of egg poisoning are essentially those of so-called ptomain poisoning, we may with reason assume that they are due to the action of putrefactive alkaloids, such as are known to develop in cheese, milk, fish, shell-fish, and decomposed meats, and not to some occult or mysterious influence, which, as a cloak for our ignorance, we denominate idiosyncrasy.

It is true that the eggs giving rise to toxic phenomena are, in most instances, apparently fresh when eaten; but when we recall that the porous shell of the egg will admit the microorganisms that cause the egg to rot, as well as various strong odors, it is easy to comprehend that an egg may appear fresh, and yet contain bacteria that in susceptible persons, and in certain conditions of digestion, may produce changes which may cause toxic symptoms.

One would be inclined to think that the yolk, because of its large fat content (32 per cent.), would be more apt to derange digestion; but, as already stated, it is usually the white of the egg that causes trouble. This may simply be for the reason, as Robert Hutchinson* suggests, in speaking of idiocyncrasy in respect to eggs, that the digestive juices of some persons apparently act in such a way as to produce poisons when eggs are introduced into the stomach. In other cases, as pointed out by the same writer, sulphuretted hydrogen may be produced during the process of digestion. The sulphur of the egg is contained almost entirely in the white, and when eggs rot, and in certain cases during digestion, alkaline sulphides are developed, and these being acted upon by phosphoric acid produced from the yolk, sulphuretted hydrogen is liberated. But the yolk alone may be responsible for the symptoms, as this portion of the egg contains lecithin in considerable quantity, from which choline, one of the putrefactive alkaloids, may be readily formed during digestion (Lauder Brunton) or from the presence of bacteria, which may have entered the egg before its ingestion. Whatever value these theories may have, one fact is significant, namely, that eggs, milk, fish, shell-fish, etc., the dietary articles with which individual susceptibility is most frequently associated, are the very ones susceptible to changes from overkeeping.

Finally, as stated above, I think the conclusion is warranted that the majority of instances of egg poisoning are really causes of so-called ptomain poisoning, *i.e.* they are due to toxic substances developed in apparently fresh eggs by the processes of digestion, or to unrecognizable changes—unrecognizable, that is, to the ordinary senses—in the eggs themselves. In this connection, we should remember, when we speak of poisoning, in certain individuals, from such an universal and valuable article of food as the common egg, as an idiosyncrasy, that this word is intended to denote our ignorance of causes, though in no degree to express disbelief in their existence (Jonathan Hutchinson).

As to the treatment of egg poisoning, there is little to be said; it must be conducted on general principles. I would only make the suggestion that, as the symptoms of ptomaïn poisoning are in many cases strikingly similar to those produced by muscarine (the active principle of the poisonous mushroom), to which atropine is a perfect physiological antidote,* the latter drug may be found useful in severe forms of egg poisoning.

Action of Radium on Vaccine Virus.—Samuele Sereni has made use of radium in experiments as to its factericidal action on various germs, and especially on vaccine virus. He exposed fresh vaccine virus to the emanations of radium for varying periods, and then made use of it in vaccinating children. He found that there was no effect on the action of the virus produced by the exposure to the rays, but that the pustules produced by the virus were entirely free from any septic suppuration, there was no inflammatory area, and no fever. He finds that this is an efficient method of purifying vaccine virus, but on account of the expense of radium not one that can be commonly used.—*Il Policlinico.*

Lesions of the Corda Equina without Sensory Disturbances.—A. M. Luzzatte describes two cases in which there was a lesion of the medullary roots which caused paralysis without sensory symptoms. In one a traumatic lesion involved the epiconus; there was pain in girdle form along the nerve trunks, and paralysis of the tibials and peronei without any zone of anesthesia. It resulted in a cure. The traumatism may have injured the anterior without the posterior roots. The other case was one of syphilitic lesion of the detrusor urinæ without disturbances of the sphincter or alteration of the vesical sensibility. Rapid recovery resulted under syphilitic treatment. Here there was a lesion of the ultimate sacral roots which enervated the detrusor by way of the hypogastric ganglion, while the sensory fibers to the bladder remained intact, coming as they do from a little higher up. The author believes that these observations speak against the theory of Muller which denied the existence of a vesical motor center in the terminal cone and places it in the sympathetic.—*La Riforma Medica.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, March 13, 1909.

SOME DRAWBACKS OF PROGRESS IN MEDICAL KNOWLEDGE.

THERE is no doubt that the marked increase in our knowledge of diseases and in the means of recognizing them by various special methods of examination has greatly increased the general efficiency of the medical profession, as compared with that of the physicians of a few decades ago. There have become apparent, however, certain disadvantages connected with such progress due to the increasing dependence upon laboratory methods of diagnosis and the correspondingly lessened care in clinical examinations and observation.

In a very entertaining paper in the *Practitioner* for February, 1909, Sir William H. Bennett discusses this aspect of the matter, taking as his text the relation of constitutional conditions to local lesions. We have recently learned so much of the causal relation of constitutional affections, such as syphilis, tuberculosis, and malignant disease, to various seemingly local manifestations that the tendency has been to attribute any such manifestations to a constitutional disease if they appeared in one who was known to be affected by the disease in question. In the words of Sir William, such individual is treated by us just as a dog with a bad name, who cannot get rid of the stigma attached to him, however perfect may have been his subsequent behavior. In one case mentioned by the author a noted surgeon made the diagnosis of a suppurative syphilitic gumma, though all the local signs were those of an infected sebaceous cyst, which the lesion proved to be on operation; the only reason for the first diagnosis was the knowledge of the fact that the patient suffered from syphilis, which knowledge obviated, in the mind of the surgeon, the necessity of a thorough local examination. In another case, that of a man whose right testicle was removed because of malignant disease, the same treatment was advised on the appearance of a swelling in the left testicle; thorough local examination, however, showed that the testicle was the seat of a syphilitic gumma, a conclusion which would have been quite evident had not the previous occurrence of a disease in the other testicle led the observers to assume the same condition to exist in the remaining organ. Again, the occurrence of a swelling in the leg after the arm of a patient had been removed for sarcoma was thought sufficient for the recommendation of a similar operation on the leg; careful examination showed that the local lesion differed in certain very important characteristics from the usual appearances of a sarcoma, and the operation was delayed on the advice of Sir William Bennett. Further developments showed that he was right, as the affection turned out to be of tuberculous nature. These instances are sufficient to exemplify the danger inherent in the tendency to trace all local affections to some already existing condition. Indeed, it is often wiser to consider such an explanation of some local lesion as the least probable one, so that consideration of other causes may be carried out with the least amount of bias.

Another point raised by the author is the danger of relying too much upon the laboratory investigations. The chief drawback of such reliance consists in the temptation to postpone even a working diagnosis from the clinical data and to await, instead, the dictum pronounced by a pathologist after an examination of the blood or of some other secretion. It is self-evident, of course, that a pathological condition found in the material sent to the laboratory may coexist very well with another pathological condition for the treatment of which the patient has presented himself, and which may be quite unrelated to the abnormalities discovered by the pathologist. Among the instances of errors occurring in this connection Bennett mentions a case in which the presence of a Widal reaction in a patient suffering from some affection of the clavicle immediately led to the diagnosis of post-typhoid osteomyelitis and to an incision over the lesion. The fact, however, that an abscess was found on the surface of the clavicle and not in its substance, and that the wound did not heal until potassium iodide was given, proved that a syphilitic lesion was the cause of the symptoms.

These instances are sufficient to illustrate the text of Sir William Bennett's paper, and it is certainly evident that he exposes a real danger in the tendencies of modern medical practice which he condemns. So far as the first point considered by him is concerned, the individual practitioner must, of course, be the man to work reforms in that direction. The other point, however, is of greater importance, and one can only repeat the words of the author in insisting upon the desirability of bringing the clinical man and the laboratory expert together at the bedside of the patient. The expert may then make any examinations he may consider proper, but the mere fact that he has seen the clinical condition of the patient should save him from reporting pathological findings without an attempt to bring them in relation with the clinical data. In such a case the clinical man will be saved many a mistaken act performed on the strength of a laboratory finding that is simply an accompaniment of the condition of the patient and not at all an etiological factor in the case.

TUBERCULOSIS IN CHILDREN.

OF all the subjects connected with disease and medicine none is of greater popular interest than tuberculosis. The reasons for this are not far to seek, for, owing to its widespread prevalence, tuberculosis has been discussed almost as frequently in

lay as in medical journals, and the man in the street has a fair knowledge of the malady, not only from the practical, but also from the theoretical standpoint. That this is the case has been of great advantage in so far as efforts to check the disease have been concerned. The intelligent interest manifested by the masses has greatly advanced the active crusade in all parts of the world against tuberculosis. Sanatoriums have been erected, various modes of treatment have been devised, including home treatment of the poor, and last, but not least, the milk and food supplies have undergone or are undergoing a thorough supervision. The consequences of all this activity have been that tuberculosis has greatly decreased, and the time, according to some optimists, is in sight when consumption will be extinct.

One of the most important of the subjects of study in this relation is tuberculosis in children, and this has been perhaps more exhaustively cultivated in Great Britain than in any other country; nowhere, indeed, has a more complete work on this phase of the tuberculosis question been published than the excellent treatise edited by Kelynack. On February 16 there was opened in London a conference on tuberculosis, the first portion of which was devoted to a consideration of tuberculosis in children. The statement was made by the chairman that 90 per cent. of crippled children owed their maladies to this disease. Dr. Shuttleworth stated that out of 1,056 children attending the London schools for defective children 480 were suffering from tuberculosis, naturally most frequently from the disease affecting the joints.

At the International Congress on Tuberculosis, held in Washington last autumn, Dr. Theodore Shennan, senior pathologist to the Royal Infirmary, Edinburgh, read a paper on tuberculosis in children, especially with reference to tuberculosis of lymphatic glands, and its importance in the invasion and dissemination of the disease. Dr. Shennan presented a series of tables which epitomized the results of an investigation of the post-mortem records of the Royal Edinburgh Hospital for Sick Children in the case of children dying from tuberculosis while inpatients of that hospital. His summary was as follows: (1) 1,085 patients came under review, of whom 41.3 per cent. died from tuberculosis. These cases were examined in two series, the first containing 105 and the second containing 308 cases. (2) The ages of the patients varied from three months to 13 years, approximately 68 per cent. being under 5 years of age. (3) The lymphatic glands were tuberculous in 97 cases (92.4 per cent.) in the first series and in 243 cases (78.8 per cent.) in the second series. The mediastinal glands were more frequently affected than the abdominal glands, and dissemination took place more frequently, apparently, from the former group. (4) Tuberculosis of the mediastinal glands was commonly unaccompanied by primary tuberculosis of the lungs, but was frequently accompanied by recent tuberculosis of these organs, in many cases evidently secondary to the gland tuberculosis. (5) In nearly half of the cases of tabes mesenterica there was no ulceration of the intestines, and in one-third of the cases there was no excavation of the lungs, although in some of them the lungs showed early manifestations of tuberculosis. In a number of cases excavation of the lungs was not followed by ulceration of the intestines, although in about half of such cases tabes mesenterica had resulted, the excavation being of some standing. (6) Primary ulceration of the intestines, in absence of any previous excavation of the lungs, was frequently found. It was usually accompanied by caseation of lymphatic glands, mediastinal or abdominal, or both simultaneously. In a large proportion of these cases the immediate cause of death was tuberculous meningitis. (7) Death was due to tuberculous meningitis in 44.5 per cent. of the cases. Apparently, the dissemination had taken place in the majority of cases from caseous lymphatic glands, and more often from the mediastinal than from the abdominal groups. In 24 cases of tuberculous meningitis caseous nodules were found in some part of the encephalon, but these had not given rise to the meningeal condition in every instance.

Dr. Shennan mentioned that his tables dealt with children of the poorer classes, and that it would be interesting to know in what respects, if at all, statistics dealing in a similar manner with children of the well-to-do would compare with those collected by him. In addition, he pointed out that in view of the wide divergencies which appear in statistics emanating from different countries, the only rational conclusion to be arrived at is that these differences depend not on the manner of treating the material but on the material itself. Statistics, therefore, representing the conditions prevailing in any one country should not be considered as applicable to the conditions prevailing in any other country, seeing that the circumstances and environment, hygienic and social, under which the inhabitants of that country live may differ widely in many important respects.

It is difficult from one series of tables to draw any conclusions of a definite nature in regard to the connection between tuberculosis of the lymphatic glands and the invasion and dissemination of the disease. That, however, the lymphatic glands of children are frequently attacked by tuberculosis is proved not only by the tables of Dr. Shennan, but by statistics collected from various sources. While post-mortem statistics cannot be too closely relied upon, the tables of Dr. Shennan would seem to show that the lymphatic glands play an important part in the invasion and dissemination of tuberculosis.

Acute Obliterating Bronchiolitis.

Chronic fibroid changes in the lungs that usually start in the interstitial tissues and result in the production of airless firm structure in the place of the spongy normal lung produce a condition well known to both clinicians and pathologists; the characteristic of the disease is its essentially chronic character, the cirrhotic changes occurring gradually in the course of an unresolved fibrinous pneumonia or after a bronchopneumonia. In the *Berliner klinische Wochenschrift* for January 4, 1908,

Fraenkel writes of an acute form of cirrhosis of the lung which is characterized by the involvement of the smallest bronchioles. The whole system of the small bronchioles that are free from all cartilaginous material in their walls was involved in the cases observed by him, and the course of the disease was uniform enough to justify its classification as a separate clinical entity. The symptoms are very similar to those of acute miliary tuberculosis—dyspnea, cyanosis, and rapid loss of strength being present in both diseases. The physical signs, too, are quite deceptive, frank dullness being absent, while impaired resonance, slight changes in the voice and breathing, and numerous fine râles are present in as marked a fashion as in an acute tuberculous process. The etiology, of course, is different and the taking of a careful history helps very much in arriving at a correct diagnosis. The disease described by Fraenkel depends upon the injury caused by the inhalation of some irritating or toxic material and the history of an occupation which exposes the patient to the possibility of such an accident is of the greatest value in correct interpretation of the symptoms. Pathologically the firm lung tissue bears a close resemblance in its general appearance to miliary tuberculosis, being studded by minute whitish or grayish points. Closer examination proves, however, that these points are not miliary tubercles but are due to the occlusion of the bronchioles by young granulation and connective tissue. The development of the disease usually occupies two to three weeks and it results in great embarrassment of breathing, that often ends with the death of the patient. Prophylaxis of the disease depends, of course, upon hygienic measures for the protection of workmen employed in trades where inhalation of very irritating material can occur. Treatment must be symptomatic in character, oxygen inhalations and stimulation being depended upon to keep up the processes of respiratory metabolism long enough for the adjustment of the organism to the greatly diminished lung area that remains after the inflammation has subsided. The disease in question is probably frequently unrecognized or is mistaken for the more chronic forms of induration of the lungs or for acute miliary tuberculosis; Fraenkel's publication should stimulate clinicians and pathologists to look for instances of the affection in the hospital wards and at autopsies. The results might prove to be of considerable interest.

Kuhn's Mask in the Treatment of Tuberculosis.

Stimulated by the favorable results obtained by Bier and his followers in treating tuberculous disease of the bones and joints by means of artificial hyperemia, Kuhn has constructed a mask to be worn over the nose and mouth with the aim of producing a hyperemic condition in the pulmonary tissues. This was described by Willy Meyer in the Medical Record of November 9, 1907, but the writer's experience had not been sufficient at that early period in the history of the invention to enable him to cite a series of illustrative cases. What use he had made of the mask, however, inspired him with faith in its therapeutic efficacy. Since that time a number of observers have reported very good results following the use of this appliance in the treatment of pulmonary tuberculosis, and in the *Berliner klinische Wochenschrift* for February 1, 1909, Dr. Gudzent speaks of a series of cases of anemia and of chlorosis as well as of tuberculosis which were treated by Kuhn's method. The patients with chlorosis and anemia were selected in order to investigate the validity of Kuhn's claims that increased blood formation and improvement in the general constitutional condition are as much a part of the effect produced by the use of his mask as the healing of tuberculous foci in the lungs. Dr. Gudzent's reports corroborate the claims made by Kuhn: in every case treated by him there was a noticeable increase in the weight of the patients, accompanied by a rise in the hemoglobin content of the blood and in the number of red blood cells. In addition, the subjective effects of the mask were very good, the patients declaring that their appetite, sleep, and general wellbeing were very favorably affected. These experiences were followed by a similar series of cases of pulmonary tuberculosis and the results obtained were quite as good, several patients being benefited so much that no symptoms of the disease remained, while in all others there was a marked improvement in the general welfare and in the local pulmonary condition. It is not improbable that these favorable results might be increased by the combined use of Kuhn's mask and of the creosote inhalations advocated by Beverley Robinson.

Typhoid Fever Without Intestinal Lesions.

It is somewhat difficult to conceive of typhoid fever without the intestinal lesions that have so long been considered typical of the disease. Nevertheless there is a certain number of cases, shown to be undoubtedly due to the bacillus of Eberth, in which the typical ulcerations of Peyer's patches are not found at autopsy. These cases are shown to be of true typhoid nature by the positive Widal reaction, the finding of the bacillus in the blood and in cultures made from the heart's blood and pulmonary juice, as well as by inoculation experiments in animals. Two such cases are detailed by E. Sacquépée and F. Chevral in the *Progrès Médical* for February 6, 1909. These cases are infrequent. In them there is a predominance of the signs of a severe infection, prostration and loss of strength, and a remarkably rapid evolution. While the intestine is intact the mesenteric glands are altered, swollen, and diffluent, and a pure culture of the bacillus of Eberth can be obtained from them. Whether this condition is due to a special virulence of the germs or a receptivity of the system is not known. It occurs by preference in children, who do not react to typhoid infection in the same manner as adults. The intestines of infants are less predisposed to ulceration than the adult intestines. The beginning of the disease is insidious and the triad of symptoms—headache, insomnia, and gastrointestinal disturbance—is present. There are stupor, enlarged spleen, rose spots, a typical typhoid temperature curve, and albumin in the urine. Meteorism and severe diarrhea are present. Complications involving the meninges, icterus, hematuria, joint complications, lung affections, and asphyxia are frequent, showing that the severity of the infection has no relation to the intestinal lesions, and indeed that the form here considered, in which no ulceration of Peyer's patches is present, may be of more than average gravity.

News of the Week.

Andrew J. McCosh Memorial.—The committee having in charge the collection of a fund to erect a memorial to the late Dr. Andrew J. McCosh reports that to February 12 the sum of $93,362.60 had been received, while pledges of future payments bring the total to $100,157.60. The committee fears that many people have been deterred from giving to the memorial because they thought that only large contributions would be acceptable. This is a misunderstanding and entirely contrary to the spirit of the undertaking. Any gift, no matter how small or how large, will be most gratefully received. The greatest tribute to Dr. McCosh has been the many small sums sent in, often accompanied with letters showing a keen personal sorrow and a loss that can never be replaced. The decision to remove the Presbyterian Hospital to the new site recommended by Dr. McCosh in his lifetime greatly increases the opportunity and scope of the memorial, and contributions are asked from all who are interested in keeping alive the life and work of one whose skill was surpassed only by his tenderness of heart for the suffering and afflicted.

Diseases of Occupations.—Gov. Charles S. Deneen of Illinois recently announced the appointment of the Occupational Disease Commission authorized by the last General Assembly to investigate conditions of different occupations with relation to the prevention of disease. Those named on the Commission are Dr. George W. Webster, President of the State Board of Health; Dr. J. A. Egan, Secretary of the State Board of Health; Mr. David Ross, Secretary of the Bureau of Labor Statistics; Mr. Edgar T. Davies, Chief Factory Inspector; Mr. James Simpson, of Marshall Field & Co.; Dr. Ludwig Hektoen, Chicago; Dr. Alice Hamilton, University of Chicago; Dr. Charles R. Henderson, University of Chicago, and Dr. Arnold C. Klebs, Chicago.

Medical Commission to Pass on Insane.—A change in the established custom has been brought about through the plea of the Illinois State Board of Charities and other agencies in an effort to remove from the general public its medieval superstition that insanity is a disgrace and to impress upon the legal authorities as well as the general public that insane patients are sick. The decision of Judge L. Rinaker of Chicago, after a conference with representatives of the State Board of Charities and eminent medical men, to give the medical commission plan a thorough trial is regarded by experts as an important advance in the modern treatment of insanity as a disease, which, like every other disease, it is stated, should be attacked with vigor in its incipient stage, before the mental or nervous storm bursts, and perhaps causes irreparable havoc. In addition to the members and representatives of the State Board, there were present at this conference Drs. Hugh T. Patrick, Harold N. Moyer, Daniel R. Brower, Archibald Church, and Sydney Kuh. Judge Rinaker asked for the cooperation of these physicians, and they agreed to submit to him a list of competent physicians from whom he can make appointments as need arises.

Board of Health Changes.—The Board of Estimate of New York recently voted to create the post of Sanitary Superintendent of the Department of Health at a salary of $7,000 a year. Dr. Walter Bensel, who has been assistant sanitary superintendent for Manhattan, will be advanced to the new position. Following closely upon the protest of the Kings County Medical Society against the withdrawal of the Assistant Sanitary Superintendent from Brooklyn, the Board of Health has passed an order restoring the office. Dr. Alonzo Blauvelt has been assigned to the place.

Cupola Operating Rooms.—Plans have been filed with the Building Department for remodelling the octagonal cupola of the Metropolitan Hospital on Blackwell's Island in operating theaters. There will be four of the theaters with apartments and accessories for the surgeons. Skylights will afford abundant light and ventilation. The cost of fitting the tower for its new use will be about $12,000. At the same time plans were filed for enlarging the hospital dining-rooms and kitchen.

Lodging House Hospital.—An "overnight" emergency hospital has been instituted at the new municipal lodging house in East Twenty-fifth street, New York. Heretofore persons in the house requiring medical aid have been sent to the Willard Parker or to Bellevue, and it is thought that the new arrangement may obviate unnecessary transfers.

Enlarging Flower Hospital.—The trustees of Flower Hospital have appropriated $50,000 for new wards to provide sixty additional beds to accommodate the greater number of patients brought in by the increased ambulance service. An important part of the district abandoned by the Roosevelt Hospital has been assigned to Flower Hospital. Until the new wards are ready the nurses' quarters will be used for wards, and the nurses will occupy a temporary home. The hospital has also installed an autoambulance service.

Outdoor Department for Mental Diseases.—A department has been opened at the Vanderbilt Clinic, New York, to which cases of incipient insanity or borderland conditions may be sent for examination and advice. Physicians referring patients to this department will be furnished, when desired, with diagnosis and suggestions for treatment. Clinics are held on Tuesdays and Fridays, from 2 to 4 P.M., under the direction of Dr. Frederick Peterson.

St. Lawrence State Hospital.—A free dispensary for the examination of poor and indigent persons suffering from incipient mental or nervous affections has been opened at the St. Lawrence State Hospital, Ogdensburg, N. Y. The individual treatment of such persons will not be undertaken, but their physicians will be notified of the results of the examinations, and advised regarding the medical and hygienic treatment. No fee or gratuity of any kind will be received, and no medicines will be dispensed or sold. The dispensary hours will be from 10 A.M. to 3 P.M. on Saturdays only. Attention is also called to an amendment to the law governing State hospitals, permitting the admission of voluntary patients to State hospitals upon the written application of the patient, and without the formality of certification and commitment as is necessary in the case of insane patients. Persons suffering from the effects of drug habits and alcoholism are not eligible for admission under this act as voluntary patients, but those who have become insane through the use of drugs or alcohol may still be committed upon a certificate of two physicians, as formerly.

New Tuberculosis Hospital.—The Board of Supervisors of Ontario County, New York, has appropriated fifteen thousand dollars for the erection of a hospital to care for advanced cases of tuberculosis. This is the fourth county hospital definitely started since the beginning of the State campaign a little more than a year ago.

The Metropolitan Throat Hospital.—During the year 1908 the total number of visits paid by patients at this hospital was 5,327, against 5,876 in 1907, a decrease of 549. The new applicants during that time were, however, 1,601, against 1,367 in 1907, an increase of 234. The thirty-sixth annual report of the hospital in presenting these figures calls attention to the scattering of population as a result of city improvements through which large districts have been cleared. Six blocks in the neighborhood of this hospital, for instance, have been cleared in order to develop the new system of the Pennsylvania Railroad, and some 30,000 individuals have removed, many of them to outlying districts beyond a reasonable range of the city hospitals.

Gifts to Charity.—The will of the late Mrs. Emma D. Cummings of New York bequeaths $25,000 to the pathological laboratory of St. Luke's Hospital, and $10,000 each to the Hahnemann Hospital, the Post-Graduate Hospital, the New York Eye and Ear Infirmary, and the Home for the Destitute Blind. Ten thousand dollars is also left to Rose Hawthorne Lathrop for the use of St. Rose's Free Home for Incurable Cancer, at Hawthorne, New York.

Dr. Simon Flexner was chosen president of the New York Alumni Association of Johns Hopkins University at the annual meeting and dinner held on Monday evening of this week.

New Superintendent of the New York Hospital.—A despatch from Worcester, Mass., states that Dr. Thomas Howell, Superintendent of Worcester Hospital, has resigned to become Superintendent of the New York Hospital and the Hudson Street House of Relief. Dr. Howell was elected Superintendent of the Worcester Hospital in April, 1902, after being at the Worcester Insane Asylum as First Assistant for five years. He is a native of Winona, Minn., and a graduate of Dartmouth Medical School.

Dr. Alfred Gordon of Philadelphia has been elected a member of the Société Médico-Psychologique of Paris.

Dinner to the Doctors Frauenthal.—The Board of Managers of the Hospital for Deformities and Joint Diseases of New York gave a dinner on March 6 in honor of Drs. Henry W. and Herman C. Frauenthal, surgeons in chief to the hospital. The dinner also marked the completion of the second year of the hospital's successful work.

Dr. Abraham L. Wolbarst of New York City has been appointed consulting genitourinary surgeon to the Central Islip State Hospital.

No Subway Smoking.—The Board of Health of New York on March 3 added a new section to the Sanitary Code of the city, making it a misdemeanor for any persons smoking or carrying a lighted cigar, cigarette, or pipe to enter the Subway. The new section also prohibits the smoking or carrying of lighted cigars, cigarettes, or pipes on the platforms of the stations or on the steps leading to them. The city magistrates have promised to assist in a rigid enforcement of the new rule.

The Woman's Medical School at Shanghai, China, recently awarded diplomas to six graduates. The school was founded a little more than three years ago, and during the past year there were thirty students. At the commencement exercises, each of the six graduates read an essay, two of them in English.

Plague in Ecuador.—During the month of February sixty new cases of bubonic plague were reported in Guayaquil, of which eleven were fatal. Thirty-one cases of yellow fever also were reported in that time, sixteen of which were fatal.

The American Society for the Study of Alcohol and Other Narcotics will hold a meeting in the Hotel Raleigh, Washington, D. C., March 17, 18, and 19, 1909. This society was organized in 1870 and claims to be the first medical association in the world to take up the study of alcohol and the diseases following its use from a scientific point of view. Over thirty papers will be presented for discussion at the meetings. A general invitation is extended to all persons interested. Details of the meeting and programmes can be had by addressing the secretary, Dr. T. D. Crothers, Hartford, Conn.

Association of American Medical Colleges.—The nineteenth annual meeting of this association will be held in the Academy of Medicine, New York City, March 15 and 16, 1909, beginning at 10 o'clock A.M. All those interested in medical education are cordially invited to be present and participate in the discussions. It is desired that the attendance on these meetings include not only medical educators, but educators in general, members of the State examining boards, and members of any and all organizations that have undertaken to study this subject.

Philadelphia Psychiatric Society.—This society, which was recently organized, has elected the following officers: *President*, Dr. Charles W. Burr; *Vice-Presidents*, Drs. Albert R. Moulton and William W. Richardson; *Secretary and Treasurer*, Dr. Wilfred W. Hawke; *Councilors*, Drs. William H. Hancker, John K. Mitchell, and Francis X. Dercum.

"Archives of Otology."—The editors of this journal announce that with the appearance of the number for December, 1908, which completed the thirty-seventh volume, the publication of the periodical has ceased. In making this announcement, the editors, Drs. Herman and Arnold Knapp, render their acknowledgments for the cordial support which has been extended to the *Archives of Otology* during the years of its publication by both contributors and readers.

Atropine as a Hemostatic.—Dr. William F. Waugh of Chicago writes that he is collecting material for a paper upon this subject and would be obliged to any one who would send him notes of his experience with the drug used for this purpose. Notes of cases in which the remedy has failed are especially desired.

The Late Dr. Bull.—The following minute was adopted by the medical board of the General Memorial Hospital on March 9, 1909: In the recent death of Dr. William Tillinghast Bull the General Memorial Hospital has lost not only the most distinguished member of its medical staff, but also one of the founders of the hospital and, since that time, one of the most loyal and earnest members of its Board of Managers, and the Medical Board desires

to express its deep appreciation of this double service so long and so cheerfully rendered.

It also wishes to place on record its own sense of great personal grief at the loss not merely of a distinguished colleague, but a warm personal friend who, in the midst of the urgent demands of a large practice, was ever ready to respond to the call of the humblest, and whose greatest reward was the knowledge that his efforts had brought relief to some poor sufferer.

The memory of his remarkable judgment and skill as a surgeon, of the beauty and strength of his character will endure as long as the hospital exists and will serve as a stimulus to the generations that follow him.

Obituary Notes.—Dr. James W. Moore of Easton, Pa., died suddenly, on February 28, of blood poisoning resulting from an ulcerated tooth. Dr. Moore was born in 1844, and was graduated from Lafayette College in 1864, and from the medical department of the University of Pennsylvania in 1869. Since 1872, Dr. Moore had held the professorship of mechanics and experimental philosophy at Lafayette College.

Dr. George Osborn Morgridge of Muscatine, Iowa, died at his home on February 12, aged 69 years. He was graduated from the College of Physicians and Surgeons in Keokuk, Iowa, in 1870, and from the State University of Iowa in 1875. He was a veteran of the Civil War, formerly a member of the faculty of the Kansas Medical College of Topeka, and a member of the Muscatine County Medical Society.

Dr. Eleanor Galt Simmons of Cocoanut Grove, Florida, died of tuberculosis of the brain, on February 2, aged 55 years. Dr. Simmons was graduated from the Woman's Medical College of Pennsylvania in 1879, and was a member of the American Medical Association.

Dr. Daniel Roberts Brower, Professor of Nervous and Mental Diseases at the Rush Medical College, Chicago, died at his home on March 1, aged 70 years. Dr. Brower was graduated from the medical department of the University of Georgetown in 1864, and for a time served as assistant surgeon in the United States Army. In addition to his professorship at the Rush Medical College, he had also for some years been professor of mental diseases at the Post-Graduate Medical School of Chicago. He was the author of a number of monographs and of a textbook on insanity.

Dr. Charles Brewer of Vineland, N. J., died at his home on March 4, aged 77 years. He was graduated from the medical department of the University of Maryland in 1855, after which he joined the Medical Corps of the United States Army, and served through several Indian wars. In 1861, he resigned and entered the Medical Corps of the Confederate Army, serving throughout the war. From 1891 to 1896 he was resident physician in the State prison at Trenton.

Dr. Thomas Cameron Walton, Surgeon of the United States Navy, retired, died at his home in Annapolis, Md., on March 2, aged 70 years. Dr. Walton, who was of English birth, was graduated from McGill University, Montreal, in 1860, and received the degree of M.D. from New York University in 1862. He was appointed assistant surgeon in the United States Navy in 1861, and was advanced through the various grades until his retirement in 1900 with the rank of rear-admiral. His active service covered the Civil War as well as the Spanish-American War; he was for some years medical director of the Naval Academy at Annapolis, and at one time was in charge of the laboratory at the Brooklyn Navy Yard. He was a member of the American Medical Association and of the Societé Française d'Hygiene of Paris.

Dr. Martin Hans Boyé, a scientist of wide reputation, died at his home in Coopersburg, Pa., on March 5, aged 96 years. Born in Denmark, Dr. Boyé was graduated from the University of Copenhagen in 1832, and from the Polytechnic School in 1835. In 1844 he was graduated in medicine from the University of Pennsylvania, where he continued his studies in chemistry. He was assistant geologist and chemist to the first geological survey of Pennsylvania, 1838-43; a joint discoverer of perchloric ether, the most explosive of all substances, in 1841; and the discoverer of the first process for refining cotton seed oil, in 1845. He was professor of chemistry and natural philosophy at the Central High School of Philadelphia from 1845 to 1859, when he retired from active teaching. He had written largely on scientific subjects.

Dr. William Wilbur Lunn of Houston, Tex., died on February 24, aged 62 years. Dr. Lunn was graduated from the Jefferson Medical College of Philadelphia in 1874.

Dr. James Scribner Brown of Manchester, N. H., died on February 22, of pneumonia, after a short illness, aged 37 years. He was graduated from the medical department of the University of Pennsylvania in 1896. He was a member of the American Medical Association, the Manchester Medical Society, and the Central District Medical Association of Concord.

Dr. Edward Andem Whiston of Boston, Mass., died on February 23, aged 71 years. Dr. Whiston was graduated from the Harvard Medical School, and served through the Civil War as surgeon of the First Massachusetts Infantry. Upon his return, he was for two years port physician of Boston, but later retired from practice to enter business life.

Dr. George W. Way of Portland, Me., died at his home, on February 12, of meningitis. Dr. Way was graduated from the Maine Medical School in 1882.

Dr. J. A. Creason of Jacksonville, Ky., died on February 17 of pneumonia, aged 45 years. Dr. Creason was a graduate of the Kentucky School of Medicine in Louisville, and a member of the Bourbon County Medical Society.

Correspondence.

OUR LONDON LETTER

(From Our Regular Correspondent.)

HUNTER'S DAY—LINGUAL CANCER—THE REPORT OF THE POOR LAW COMMISSION—NATIONAL CONFERENCE ON TUBERCULOSIS—LIVERPOOL TROPICAL SCHOOL; RETURN OF DR. THOMAS; RECEPTION TO DR. BOYCE—OBITUARY

London, February 17, 1909.

The Royal College of Surgeons had a gala day on Monday. As I mentioned in my letter last week, the Prince of Wales had accepted the Honorary Fellowship of the college. In accordance with the program he attended on Monday and was formally enrolled. He was accompanied by the Princess, and the royal party were received by the assembled councilors, together with the Earl of Rosebery, who is an Honorary Fellow. All Fellows wore their robes. The secretary read the minutes of the election, the president handed his diploma to the Prince, who signed the roll of

Honorary Fellows and donned the robe. The assembly then proceeded to the lecture theater to hear the Hunterian oration. Hunter's day, February 14, this year falling on Sunday, was celebrated the following Monday. The theater, as you would expect, was crowded with Fellows, members, and their guests—a large and distinguished audience. The president, Mr. Henry Morris, was the orator, so the senior vice-president, Sir Watson Cheyne, took the chair, with the Prince and Princess on his right and left. At the opening of his oration Mr. Morris said: "My first duty is to request your Royal Highness to accept the grateful and respectful thanks of this college and of the surgical profession of England, which this college represents, for the great favor you do us by honoring the memory of John Hunter, whose inheritors we are, by your presence here to-day. We shall ever remember with great pride that you, sir, have deigned to accept the diploma and to sign the roll of the Honorary Fellowship of the college and that the graciousness of this act has been deeply accentuated by its having been performed in the presence of Her Royal Highness the Princess of Wales. I will also venture to add that your Royal Highnesses' visits of sympathy and compassion, such as those made by you during the last few days to several of the London hospitals—visits which give so much gratification and delight to the patients and so much countenance and encouragement to the management and staffs—tend to qualify you, sir, for the diploma, for in the noblest spirit and best sense of the words you have been engaged in that essential part of the curriculum known as 'walking the hospitals.'" I may add that this was received with laughter and cheers, on the subsidence of which the president proceeded with the more serious duty of the oration.

John Hunter's name, he said, was not signalized by one striking discovery, but had an influence profound and far-reaching upon many sciences. His contributions to human and comparative anatomy, to the natural history of plants and animals, to geology and paleontology were of such value that through his labors progress was made in each of those sciences. He was the only great natural philosopher between Newton and Darwin. He was one of the class of untaught geniuses who had risen to the highest intellectual achievements by their own unaided power. The orator then proceeded to trace the influence on Hunter of the intellectual movements in France, England, and Scotland in the eighteenth century, leading up to his combining in an exceptional way the inductive and deductive methods in his philosophy. Hunter was a thinker rather than a scholar. He saw that for a complete scheme of knowledge deduction and induction were complementary, and when the time came that all the intellectual resources of man were fully developed and perfectly coordinated the two methods would not be regarded as hostile, but would be combined in a single system. The president disagreed with the opinion expressed by Buckle in his "History of Civilization," that Hunter's use of both methods was due to his spending his youth in Scotland, where the deductive method prevailed, and his after life in England, which had adopted the Baconian philosophy. There was no evidence that Hunter came under the influence of Scottish philosophical teaching in his youth. Mr. Morris took the view that the combination of the two methods was due to the natural scope and bent of Hunter's mind and to the nature of the subjects with which he dealt. It was not as a logician that he excelled, but as an observer and experimenter.

In the evening the Hunterian Festival Dinner was held in the college.

The Hunterian Society also observes Hunter's day by an oration, which was this year delivered by Dr. W. Rawes, whose subject was "Psychiatry—a Retrospect."

Mr. Butlin on the 12th inst. exhibited at the Clinical Section, R.M.S., his interesting and important collection of illustrations of "Early Carcinoma of the Tongue" and the conditions likely to be mistaken for it. Speaking of the operations he had performed for it—a total of 200—he said probably Mr. Whitehead was the only surgeon who had operated on a larger number of cases. It was the bad prognosis which had drawn his attention to the importance of early diagnosis and treatment. He had at one time spoken of a precancerous stage, but both patients and doctors were reluctant to resort to operative measures when it could not be stated that cancer decidedly was present. Five years ago he sent to Dr. Bashford material from precancerous condition, and it proved to be well-marked carcinoma. From that time he had had drawings made of all cases and had insisted on the necessity of operation. Since then he had operated on 14 of these early cases, of 12 of which the drawings were shown; three had died—one of nephritis and heart failure, but with no recurrence; one four years later from secondary affection of the glands, and one for which early operation was declined. Eleven were alive and well at periods from eight months to four and one-half years. There was no local recurrence in any of the 14 cases, although eight had lived from three to about four years. The glands were removed in nine of them. The diagrams showed the extent of the operation was out of proportion to the cancer, but this was to remove the leukoplakia and chronic superficial glossitis. Mr. Butlin said there were several forms of early cancer of the tongue, from which he could separate five as the most distinct. After describing them, he remarked as to radium that the air was charged with the emanations which had been positively asserted had cured epithelioma of the tongue. Until quite recently he would have declared that those best able to judge would have concurred in stating that there was no evidence to prove that radium could cure lingual cancer, and he might have added that the only case he had treated by it ended disastrously. But within a few days he had seen a case in which a typical epithelioma of the inside of the cheek had so much improved that it looked as though it would be cured. But radium must act very differently from any remedy at present understood, if it only cured locally, but followed and eradicated the disease from the glands and intervening channels.

Mr. Barker congratulated Mr. Butlin on his results. He had himself studied the precancerous stage and when in doubt extirpated the parts affected. In only one case was cancer absent. He was not sure that the glands must be removed, for many cases had recovered without removing them. There was great difference in the degree of malignancy, and perhaps some successes depended on the cases being of the low malignancy.

Mr. Walter Spencer considered that the small-celled infiltration which runs down between the muscle fibres proved malignancy and indicated early removal of glands. Therefore the patch should be completely removed and microscopical examination made before excising the glands.

Mr. Clutton supported Mr. Butlin in all he had said, both as to the growth and the glands.

Mr. Bowlby had always removed the glands except in one case, in which the patient objected. That was eight years ago, and there was no recurrence, but he considered it exceptional. He had seen the patient referred to by Mr. Butlin as treated with radium, and he did not regard it as a malignant case.

Dr. Bashford said one of the first discoveries of the Imperial Cancer Researchers was that a minute piece of growth, the size of a pin's head or less, could, by engrafting, reproduce all the evidences of cancer, including metastasis. He regarded Mr. Butlin's work as one of the first fruits of the investigation. The growth was often spread out fan-shape in the deeper structures, indicating a more extensive operation than the surface appearance suggested. New growth was modified by constitutional changes, and these might be sudden and favor rapid dissemination. We had no means of judging how a tumor might behave either from its biological characters or the constitutional symptoms set up.

Mr. Butlin, replying, admitted some cases did not lead to metastasis, but they could not be distinguished, so he did not think it safe to leave the glands. The late Mitchell Banks 25 years ago urged removal of the axillary glands in mammary cancer, a proceeding now generally adopted. He looked for the same practice to become the rule as to the glands in cases of cancer of the tongue.

This week will be notable to many social and medical reformers on account of the appearance of the long-expected report of the Royal Commission on the Poor Laws and the relief of distress. The commission was appointed in December, 1905, and the report was only issued on Wednesday as a heavy Blue Book, a thick volume of 1,252 pages, folio. It may be called reports, for there is a report of a minority, who dissent from much which the majority recommend. Between the two there is abundant provision for thought, and we may expect a good deal of controversy. The commissioners determined at the outset to consider principles,

to avoid details and to accept, as far as possible, recent or current inquiries into cognate subjects. It is proposed to abolish Boards of Guardians and set up in their place—but with largely increased duties—"public assistance" authorities. Importance seems to be attached to the change, and as it is held that it will remove some of the objections of the poor to the present methods, it may be well to signify the complete reorganization by a new name. The proposals as to medical relief will attract the attention of those occupied in it first of all. On these the majority and minority do not agree. The former recommend a provident basis. The latter think this would not be economical, but probably extravagant, and would continue the present outdoor medical service. At the same time, they recommend a unified medical service on the lines of the public health service, but are not very definite as to its extent or how it is to be established. No doubt much discussion will take place before Parliament seriously takes the report into consideration.

A conference on tuberculosis, which calls itself "national," has been held during the week. It was opened by Sir W. Treolar on behalf of the Lord Mayor. Various opinions were put forward. Sir F. Channing deplored that notification was not compulsory, on which the Rev. R. Wakefield said the matter should be handed over to the sanitary authorities. Dr. Shuttleworth dealt with the disease in children, maintaining that it was the most common cause preventing school attendance, particularly the special schools for defective children. Out of 1,050 attending these schools 480 were suffering from tuberculosis, the most common manifestations being hip disease (195 cases), spinal (186) and knee joint (80). Dr. Jane Walker dealt with "communicability of consumption." Surgeon-General Watt, who presided on one day, said he had found many prisoners at Borstall had wanted to go into the army, but could not on account of their low physique, and consequently fell into crime. Better housing and hygiene had so changed the condition of the troops that consumption had practically disappeared. Mrs. Rushton said the campaign against consumption in Ireland was educating the people on the best means of prevention.

Archdeacon Sinclair urged that the hearty support of the medical profession and its anxiety to make its experience and knowledge valuable to the country left them the duty to rouse the public interest in the matter.

Yesterday Earl Carrington spoke of the danger of infection through milk, and said the Board of Agriculture (of which he is president) was fully alive to the question of tuberculosis in animals and hoped to reduce the risks in the direction suggested by the Royal Commission.

Dr. F. S. Toogood of the Lewisham Infirmary said he had striven for open air for 20 years and was long thought a fresh-air crank. He had an open-air ward, and during certain winds the rain was blown onto the beds; so he put on mackintoshes, leaving the patients' faces uncovered. During the heavy snow last Christmas six inches of snow was on the beds one morning, and his patients were comfortable and cheerful. The most hopeless part of this work was, that after being so much ameliorated as to go to work again, the patients returned to the old environment. He advocated an adequate housing bill, better ventilation in factories, workshops and dwellings, with teaching of hygiene in schools.

Dr. Wolferton Thomas has arrived home from Manaos after three and a half years' work on yellow fever for the Liverpool Tropical School. You will remember that his colleague had to be invalided home at an early stage of this expedition (the second), and he himself suffered from the disease, but was able on recovery to continue the work along the Amazon River. Dr. Thomas regards the outlook as favorable for the eventual extermination of the disease, but his report will not be ready for some time, as he needs rest and change, part of which he may obtain in his native country, Canada, and perhaps will pay you a visit in the United States.

Sir Rubert Boyce, dean of the school, was entertained at luncheon on Tuesday at Liverpool before leaving, at 24 hours' notice, to take up the appointment under the Colonial Office of Sanitary Commissioner to Barbados and Trinidad. The American Consul called him "the valiant knight of humanity" on account of his work in New Orleans.

The death is announced of Lieutenant-Colonel Sir George King, M.D., Aberdeen, 1865, late superintendent of the Royal Botanic Garden, Calcutta, from 1871 professor of botany at the Calcutta Medical College and superintendent of the Government cinchona plantation at Darjiling. In 1891 he was appointed Director of the Botanical Survey of India. In 1890 he was made a C.I.E. and advanced to the K.C.I.E. in 1898. He was also a Fellow of the Royal Society. He wrote the "Manual of Cinchona Cultivation in India," and other works connected with botany.

Dr. John Tawse Nisbet of Liverpool, while attending a patient, was seized with syncope and died at the bedside on the 13th inst. He was M.D., Edinburgh, 1889, and formerly on the staff of the Children's Infirmary of Liverpool.

Mr. Alfred Temple Spanton of Birkenhead died yesterday suddenly at the age of 30. He was educated at Cambridge, took the license of the Edinburgh College of Surgeons, and had held various resident offices.

LETTER FROM ROME.

(From an Occasional Correspondent.)

INFLUENZA—THE EARTHQUAKE IN SICILY—HEALTH OF THE POPE—IN MEMORIAM OF THE PROFESSORS AT THE UNIVERSITY OF MESSINA.

Rome, January 23, 1909.

We have not yet this winter seen the Spanish steps and the Piazza di Spagna mantled in a good fall of snow, a very pretty sight with the towers of the Church of the Trinità de' Monte above and the tiers of flower stands with their variegated colors below. But we have had and are still having a visitation even less welcome than snow and slush under foot in the shape of coughs and colds, the appanage of an epidemic or prevalence of influenza in its milder form through which we are still passing. I think physicians are too inclined as a general rule to pass over lightly the extreme treacherousness of influenza and how quickly and unexpectedly a serious complication may arise or a fatal issue take place from syncope or heart failure, without any complication having actually declared itself.

The great mortality, estimated at from 100,000 to 200,000, and vast amount of disease and suffering caused by the earthquake and cataclysm, with the destruction of the two principal towns and many villages about the Straits of Messina, are prominent in the professional as well as in the lay mind. The best way to dispose of the tens of thousands of putrifying dead bodies would be to burn them, and thus prevent any outbreak of disease or epidemic that might result from them, and at the same time purify the places by fire. Some comment has been caused in Rome by the fact that the American Ambassador has sent three Italian physicians under the direction of a fourth Italian physician, who remains in Rome, to Sicily, and that no American physicians were called upon to take part in the work of relief, especially as the $800,000 was voted by Congress and large sums of money were and are being subscribed privately all over the country, thus making it a national work. There are able and distinguished American physicians in Rome, Florence, and Naples. We might mention Dr. W. Wilberforce Baldwin, Dr. Halsted Boylan, Dr. Parke, and others. Dr. Baldwin, the physician of royalty, and the longest established American physician in Italy, would have been a fitting person to give counsel or head a relief expedition.

The health of the Pope, about which so much is being written and said, is by no means as precarious as report would have it. His Holiness is, of course, at times suffering from the infirmities of his age, which leave him with less resistance than he once had, and the unpleasant gouty twinges in the articulations are only the ills that flesh is heir to. Being the unfortunate possessor of a uric acid diathesis and advanced in years, you may expect to hear from time to time of certain indispositions attendant upon such conditions, but which need not, and probably will not, shorten his days. He is quite well again, and busy with audiences and ecclesiastical matters, making provision for the children survivors of Messina, and taking a lively interest in his hospital, the "Ospedale Pontifico," filled with the sick and wounded from Sicily, among whom the mortality is very high, doubtless due to the exposures and privations undergone, to say nothing of the journey to Rome.

The meeting of the Medical Faculty of the Royal University on Monday was devoted to eulogizing those professors of the Messina Athenæum, who were victims of the catastrophe. Most of them had been "docents" in the University at Rome before giving instruction in that of Messina

THE ZOOPHIL-PSYCHOSIS.

To the Editor of the Medical Record:

Sir:—There is much thought in Dr. Dana's observations in the Medical Record that inordinate love of the dog and other animals at times becomes obsessive insanity.

At crossroads towns, where advantages of schooling and civilization are lacking, dogs, next following immature whiskey, are probably the leading factor in feuds and neighborhood fatalities. It is of common occurrence for some man to throw a stone or stick at an egg-sucking cur, or for some mischievous boy to pour turpentine upon or tie a tin can to some mangy mongrel, and thus within an hour bring out the entire community armed to the teeth and ready for the fray. Indeed, in Greater New York, if report is true, a week or two ago a schoolboy kicked a street fice, and, as if by magic, men with pistols, dirks, clubs, and stones appeared upon the scene, and some half-dozen adults were killed or seriously injured.

Where intelligence is reversionary or incapable of undergoing adaptative evolution, dogs and other pets receive passionate interest and hypertrophied devotion, because, to owners of this degree of intelligence, people in general give no attention, and heed not their fuss, even shun their flattery, consequently, the patient, slavish dog may be the sole recipient of both the flailing and the affection of these strange extremists. Homicide from quarrels over dogs is probably more frequent than death from hydrophobia.

New York. N. B. Jenkins, M.D.

Progress of Medical Science.

Boston Medical and Surgical Journal, February 25, 1909.

Anterior Metatarsalgia; Its Causes and Relief.—N. Allison says that the predisposing causes of this condition are for the most part a lack of muscular use of the anterior part of the foot and the tight bandaging and splinting of the anterior foot in a shoe. Secondary to these is the influence of increase of weight which comes with adult life and the pursuit of sedentary occupations. The causes which actually produce the pain are anatomical. Morton, after whom the disease is named, showed that the pain arises from the fact that the fifth metatarso-phalangeal joint is much posterior to the fourth, thus bringing the base of the phalanx of the little toe opposite the head and neck of the fourth metatarsal. Accidental compression of the external plantar nerve is thus produced, owing to the greater motility of the outer metatarsal bones. The general mechanical factors involved in the production of the malady are elaborated by the author, who gives in his paper some excellent illustrations. His treatment consists of support and developmental exercises, any error in footwear being corrected. The appliance he recommends is made on a cast of the dorsum of the foot which is taken as high on the dorsum and sides as the medio-tarsal joint. Under the anterior arch of this cast a depression is cut, deep or shallow, circular or elliptical, to suit the individual case. This depression should have the greatest point of concavity behind the location of the heads of the second and third metatarsals and should be so cut that it approximately restores the normal relationship of the metatarsal bones. Into this depression the leather worker fits either a hard leather or a compact felt pad and to this he sews a circular leather bandage which is made of light nonstretchable leather, the dimensions of which are marked out by the surgeon on the cast of the foot. It will be found that this slight hallux valgus which exists in most cases will aid in keeping this pad and bandage from slipping backward as the leather is made to fit closely the shape of the foot at the head of the first metatarsal. The bandage is laced together through holes cut in the two edges of the dorsum of the foot with a light string. No eyelets should be placed in these holes, and the leather should be soft and non-creasable. Advantages claimed for this appliance are that it is light, durable, gives firm support where most needed, and is held constantly in the right spot.

Nerve-Strain of School Children.—L. W. Flanders describes the typical modern school child with its multiplicity of school duties and consequent nerve disorders, and offers the following suggestion for its avoidance. No child should enter the public school until he is seven years old. There should be separate rooms for study and recitations. At least once a year there should be an examination of the eyes by a competent oculist, furnished by the State. There should be a more elastic curriculum for pupils in feeble health. There should be a most careful examination of children by both teacher and parents, to see that no more mental work is required of them than they can endure without detriment. Better a race of healthy fools than of wise invalids. The best of teachers should be selected and they should be well paid.

Death from the Electric Current from Turning on an Electric Light.—F. E. Jones relates the case of a healthy young man of 21 years who worked in a machine shop tending a small forge. He stood on a gravel floor mixed with considerable iron chips. Over the forge hung a 16-candlepower, 110-volt incandescent lamp. He reached to turn the light on, uttered a sudden cry, was found stiff and rigid, with one hand clutching the lamp, and leaning against certain iron bars. The contact being broken, he fell to the floor. It was supposed that death was instantaneous. An examination of the wiring system supplying the light showed that the wire to the lamp had come in contact with a wire carrying a voltage of 2300 in connection with a street car system near by. The fuse of the lamp was in good order. These fuses are made of soft metal which breaks when a sufficient amperage goes through them. It is said that the soft metal ages and becomes less resistant, allowing electricity to pass through without burning it out. It only takes from four to five amperes to kill a man. Just how the high voltage current touching the secondary wire jumped across the lamp socket is hard to tell, except that the man was standing on ground highly impregnated with metallic dust and so formed the shortest conductor to the ground. Some interesting facts in connection with commercial electricity are given in the article.

New York Medical Journal, February 27, 1909.

The Treatment of Malignant Growths by Injections of Mercury, Arsenic, and Iron.—W. L. Harris records his experience with a few years' use of the therapy indicated. He has made it a practice to use on every patient he has operated on for malignancy, a course of injections of the remedies named. In far advanced cases he has not urged it. For sixty days after operation he has injected daily one-half grain of a soluble iron salt and one-twenty-fourth grain of arsenious acid. Every ten days he has injected two and a half grains of salicylate of mercury until ten grains have been given, then one-half or one grain every twenty days for the first year. In the second year he gives similarly, one grain doses until ten grains have been taken, and then one-half grain every month. More recently he has used succinimide of mercury in doses of one-fifth grain hypodermically every five or ten days for ten doses, then every fifteen or twenty days. The iron and arsenic injections are repeated from time to time. Of this form of therapy the author has high expectations.

Is the Human Body Supplied with an Autoprotective Mechanism?—C. E. Sajous says that man is supplied with an autoprotective mechanism which includes: (1) The immunizing center, an organ of special sense annexed to the heat center, both centers being located in the pituitary body; (2) the thyroparathyroid glands; (3) the adrenals; and (4) special nerves which connect the immunizing center (through the heat center) with these two sets of organs. The immunizing center, which governs the autoprotective mechanism, is the developed "osphradium" or "test organ" described by zoologists in mollusks and certain ancestral vertebrates. While the osphradium of primitive animals tests their respiratory fluid, sea water, its prototype, the immunizing center of higher animals, including man, tests the blood, also a respiratory fluid and a qualitative homologue of sea water. When the functional activity of the immunizing center is increased through the presence in the blood of some toxic, *i.e.* wastes, toxins or endotoxins, mineral and vegetable poisons, certain venoms, drugs, etc., capable of exciting this center, it stimulates correspondingly the heat center and thus awakens the immunizing process. Fever indicates that the autoprotective mechanism is active. The rise of temperature is due to the increased production of thyroparathyroid and adrenal secretions, and the resultant increment of metabolic activity. The immunizing process is a consequence of this hypermetabolism, all the immunizing agents, plasmatic and cellular, being produced in greater quantities. Absence of fever in toxemia of any kind is due to inability of the immunizing center to react under the influence of the toxic, owing to deficient sensitiveness (inherited or acquired) of this center, or to the fact that the toxic is itself a paralyzant or anesthetic of its sensory elements. Excess of fever (above 105.5° F.) is due to excessive excitation of the immunizing center and a corresponding overproduction of defensive bodies. This condition exposes the red corpuscles and the endothelial cells to proteolytic destruction (hemolysis and autolysis) along with the pathogenic substances or bacteria.

Journal of the American Medical Association, February 27, 1909.

The Abuse of Surgery.—J. L. Wiggins remarks on the lack of training of many would-be surgeons at the present time, and says that the claim that one must learn surgery by practical experience is not valid now as it was twenty years ago. Attempts that were permissible or commendable then would be inexcusable now. There is, moreover, a wide difference between the words "operator" and "surgeon," and the recent graduate, except in rare instances, is not competent to operate. No medical man would choose an occasional operator to perform an important operation on himself or family, and, he asks, is not the public entitled to the same protection? There should be some minimum qualification for any one who professes to practise a specialty and, while he does not think it practicable at present to adopt for this country the measures proposed in Germany and Austria, he holds that one who wishes to specialize in surgery should file notice of his intention with the State Board and be furnished by it with a list of accredited postgraduate schools. His course of special postgraduate study should be for not less than a year and should give him a firm, practical, as well as theoretical grounding for his work. No one should be permitted to practise surgery or call himself a surgeon unless specially licensed. One advantage of such a rule would be to limit the number of surgeons and give those licensed full opportunity to keep up and increase their skill. Every surgeon, moreover, should have his trained assistant and his skilled anesthetizer who should share his responsibilities in their respective departments. He owes it to himself, to his consultant, and, most of all, to his defenseless patient, that every possible avenue of danger is safeguarded. Against the alleged difficulty of obtaining trained assistants, he says he knows of at least a score of men in smaller cities who, engaged in general practice, have found it possible to attain a high degree of proficiency as assistants. The position of the general practitioner is assured, the specialist can never displace him and the welfare of the community is in his keeping. He is the first consulted; and when he deems a disease amenable to surgical treatment his opinion is sought as to the surgeon who can safely be trusted. He may err, but there is little danger when he is actuated by honest impulses.

Publicity in Public Health Work.—E. C. Levy remarks on the importance of educating the public as to what is being done by the public health authorities of their own municipalities, and cites as an example of how it should be done, the instruction and creation of public sentiment in regard to tuberculosis which is being carried on at present in most parts of the country. The more completely the public has the workings of the local health department placed before it the more active and cordial will be the support given. He speaks, however, of two classes of difficulties met with by the health officer in utilizing the newspapers on the support of which he must chiefly depend. One of these is the difficulty of getting the papers to follow up any of the work of the health department in a systematic way, in spite of editorial good will; the other is the tendency to sensationalism which always stands in the way of such publicity as the sanitarian most desires. Not even by writing the article himself can he always insure against sensationalism; there still remain the possibilities of editorial introduction and of flaring headlines not borne out by what appears beneath them. He gives examples of such experiences of his own. Still these drawbacks are, on the whole, more than counterbalanced by the advantages of newspaper publicity, and even the "scare heads" may sometimes be the only means of securing a hearing from those who need the information, but can only be induced to give their attention by such highly seasoned presentations of the facts. But if newspapers err sometimes in this way, there is never a time when they will not willingly give space to public health questions. There are other methods, bulletins, lectures, etc., that may be utilized to advantage, though these too may have some drawbacks. The health officer will always find some to criticise his methods, to charge him with self-advertising, etc. These he must endure, being always on his guard to give them no real excuse.

Typhoid Perforation.—A. J. Brown calls attention to two new signs which seem to him to be important in the early diagnosis of typhoid perforation. These are what he calls the "dipping crackle" and the tendency of the pain and tenderness to approach the side that is lowermost when the patient is turned on the side. Both of these signs are illustrated by cases. The "dipping crackle" sign is heard on placing the bell of the stethoscope over the right iliac fossa and dipping suddenly with it as in dipping palpation. A very fine crackle is then heard which sounds much like a fine crepitant rale, or as if two sticky surfaces were being drawn apart. This was present in three of his seven cases, and appears to him to be a rather valuable confirmatory sign, as it seems to be due to the fact that in dipping suddenly the parietal and visceral layers of the peritoneum come in contact for an instant, and apparently the inflamed surfaces stick together for a moment and then pull apart. He has never found the sign present over an area of more than two inches in diameter, and never later than four hours after the initial symptom, presumably because the accumulated gas prevents the surfaces from coming in contact. The second sign is due to the gravitation of the extruded contents of the intestine. On the occurrence of a sudden, sharp pain in the lower part of the abdomen, and especially in the right iliac fossa, accompanied by tenderness, with or without rigidity, the abdomen should be carefully examined and the area of the tenderness mapped out. The patient should then be turned on the unaffected side, and if, in from fifteen minutes to half an hour, the tenderness has moved one or two inches, or if, at any time, the tenderness and rigidity become marked, immediate operation is indicated.

Cerebral Arteriosclerosis.—G. A. Moleen describes the symptoms, diagnosis, and treatment of arteriosclerosis of the cerebral vessels, and remarks that an important element in its etiology is the toxic one, which is most often due to syphilis. Whether high blood pressure is a cause or consequence of arteriosclerosis is a matter in which opinions differ, but it is sufficient to observe that they generally exist together. Two points, however are deserving of mention: (1) With the thickening of the vessel wall the elasticity must be impaired, causing greater resistance and more continuous strain; (2) it also should be borne in mind that a tendency to arteriosclerosis is an individual peculiarity, possibly through inheritance. There are two forms of arteriosclerosis recognized—the diffuse and the nodular—both of which may coexist in the same vessel. The condition of the general arterial system, however, is not a proof that it exists everywhere, and that the cerebral vessels may not escape. With the nodular form aneurysms are often produced, and occur either as miliary aneurysms, affecting the smaller vessels, or larger ones elsewhere. They are most frequent on the left side of the brain, and a point worthy of attention is that they may be temporary, the dilated vessel returning to its normal dimensions and injury not be demonstrable postmortem. In the diffuse form of arteriosclerosis, when uniform, the changes are mainly nutritional, but may, as the thickening increases, affect one side more than another. Thrombus may occur, but partial or incomplete occlusion is more frequent, producing softening. Of the general symptoms, headache stands first, usually dull, not throbbing, appearing in the morning and going off as the day advances, except in syphilitics, in whom it is usually severe and nocturnal. Dizziness and vertigo are next in importance, numbness, tinkling, twitching, weakness in the limbs or hemiparesis and disturbances in articulation are also common. The diagnosis is not difficult if the condition be carefully studied, or if localizing symptoms be present. The ophthalmoscope is of greatest service, revealing arteriosclerosis of the retinal vessels. The paradoxic reflex, lately described by Gordon, elicited by firm digital compression of the calf muscles at about the insertion of the gastrocnemius while the foot is resting and relaxed may be of value; it appears before the Babinski symptom; if the pyramidal tracts are irritated there is extension of the toes, with some separation; and if not; they are flexed and almost immovable. Stupor or coma are not infrequently associated with cerebral vascular disease, and low blood pressure, combined with a slow pulse during coma, should speak rather for sclerosis than uremia. In treatment, the all-important factor is rest and quiet as soon as definite symptoms appear. The diet should be restricted and digestible in quality, as these patients are inclined to overeat. The plan Moleen adopts is, first, absolute rest in bed; second, saline catharsis, preceded by calomel if necessary; third, potassium iodid in gradually increasing doses till 50, 60, or 70 drops a day are given. Then it should be diminished until 30 or 20 drops are given, and then discontinued. A tonic may then be given, such as strychnine, beginning with 1-30 of a grain, and later increasing to 1-24 or 1-20 of a grain. If the hemoglobin is low, iron and arsenic may also be useful, alternated with the above. If syphilis is present it should be combated with mercury alone as soon as possible, followed by iodides and later tonics. With sudden weakness,

twitching, or spasm coming on suddenly, nitroglycerin or sodium nitrate may be used with advantage until by saline catharsis the hypertension can be reduced. Thyroid extract has also been recommended for the hypertension. Modeen speaks also favorably of thiosinamin, which he has used with seemingly good results. It is given in substance or with milk sugar in increasing doses of from ½ to 2 grains. He thinks much can be done if the patient is obedient and the physician understands the case. The alternative may be stated as six weeks or more in bed, on the one hand; and death, life in a wheel-chair, or permanent defectiveness on the other.

The Lancet, February 20, 1909.

Water as a Diet for Premature Infants.—A. G. Cole and J. E. Prentis delivered a woman at the sixth month, of a male child. It was too weak to take the breast, so breast milk was withdrawn and fed to it, but the milk was not digested. He was then fed with water containing a little sodium bicarbonate and aromatic spirits of ammonia were given in addition. Any attempt to add even the most dilute foods to the water was followed by indigestion. For four and a half days the child lived on this water diet and began to increase in vitality and was finally able to digest very weak peptonized milk and water. Alternation of the two diets was followed for about a month. He weighed two pounds at birth, and had now gained over ten ounces. On the thirty-first day he suddenly became cold and rigid, with fixed jaws, slow and shallow breathing, feeble and rapid pulse; no twitchings, but the legs could not be drawn up. Under the usual measures he rallied somewhat, but on the thirty-fourth day he died in an attack similar to the above. The authors say that it may be presumed that the continuation of life and maintenance of the natural eliminative functions were due to the water assimilated plus the small continuous doses of ammonia.

Henoch's Purpura and Intussusception.—H. Lett describes a case of this nature, referring back to Henoch's statement in 1874 that he had met with a series of cases of purpura which were associated with intestinal colic, vomiting, intestinal hemorrhage, and frequently painful swelling of the joints. In the author's case the immediate cause of death was septic peritonitis following operation. He analyses the literature of such cases and notes that there is a certain number in which diagnosis is extremely difficult, especially those cases presenting a purpura but in which the existence of intussusception is doubtful. Many of the symptoms of this intestinal condition may be present, even in its absence. If its existence is assumed and the skin lesions are extensive, attempts at reduction should be made by means of injections into the bowel and laparotomy reserved as the last resort. A laparotomy is complicated by the fact that, owing to the general systemic condition, the after-condition of the wound may become a serious factor. Intussusception is a rare complication of Henoch's purpura, and in the majority of cases of this intestinal lesion a tumor can be palpated. Unless such palpation is possible, it would hardly seem advisable to open the abdomen. The wound may become purpuric and there is on record at least one case of fatal hemorrhage from the wound itself.

An Historical Instance of the Adams-Stokes Syndrome Due to Heart-Block.—G. A. Gibson and W. T. Ritchie record the history of a clergyman of 75 years who, while on a train, was suddenly attacked by unconsciousness and muscular rigidity. His pulse was only six per minute and registered regularly every heart-beat. In the course of a few hours the attack passed off. In the course of the next few months he had a series of such attacks and it was possible to examine him closely. He finally died in one of the attacks. Examination had shown during life a partial heart-block. There was a distinct cervical venous pulse of the auricular type. The heart was enlarged and dilated. Vessels were somewhat thickened. The first heart sound was replaced by a murmur heard all over the precordium, especially loud at the apex. The second sound was loud and ringing, especially about the aortic cartilage. Following every second sound, two additional sounds were heard, due probably to pulsation of the auricles. There was no absolute dissociation of the ventricular and auricular movements, the ventricular pulsation being immediately preceded by an auricular impulse although the interval between auricular and ventricular pulsations was not always exactly the same. The arterial pressure was extremely high during the systolic period, reaching to 230 and falling to 75 during the diastolic period. Autopsy confirmed the diagnosis as to the condition of the heart and vessels. The case was one of, at first a partial, and later a complete heart-block.

British Medical Journal, February 20, 1909.

Reflex Cough.—J. R. Bentley records the case of a severe cough following pertussis in a boy, which was finally proven by exclusion to be due to a foreign body imbedded in cerumen in the right ear. In a few hours the boy was free from a cough which had lasted for over a year and a half. He had had no symptoms referable to the ear.

Unna's Method of Treating Leg Ulcers.—This is described by G. Pernet. The ulcer is cleaned up with a 1-2,000 solution of bichloride of mercury solution. Iodoform is then dusted on the ulcer floor only. Unna's gelatine paste liquefied in a hot water bath is then painted on the parts surrounding, but not on the ulcer itself, well beyond the latter, and on all parts showing redness or discoloration. To make the paste, 15 parts of gelatine are soaked in 45 parts of water for two hours. A gentle heat is applied, with the addition of the glycerine till dissolved. Then the zinc is stirred into a smooth consistence and the whole allowed to cool. Double-headed bandages in one piece, rolled from either end, are used, similar in material to those used in plaster-of-Paris work. Such a bandage is wrung out in warm sterile water and its middle is placed on the leg opposite the ulcer. The first turn is made with pressure enough to diminish the diameter of the limb, the bandage being brought well over the ulcer. It is then taken round the leg with firm pressure, especially over the actual ulcer, allowing the turns to take no more or less where they list, the two hands being used for this purpose, and the turns being evenly applied, an easy matter, as they are wet. Meanwhile the liquid paste is painted on the bandage as it is wound. A few figure-of-eight turns can be taken under the foot to fix the whole. Renewal of the bandage depends on the amount of discharge. The crucial point of the whole application is firm pressure on the ulcer edges in order to bear them down.

Early Diagnosis of Cancer of the Tongue and Results of Operation in Such Cases.—H. T. Butlin makes the following classification: (1) A little plaque like a hard sore, smooth and polished, but neither ulcerated nor excoriated. (2) The transformation or replacement of a simple ulcer by a cancerous ulcer, which only differs from the simple variety by feeling a little stiffer and a very little firmer. (3) The transformation of an entire plaque of leukoplakia into a plaque of cancer. The difference is marked by very slight thickening, a denser white and a furrowing or fissuring in various directions, but without ulceration or excoriation. (4) The transformation of one small area of leukoplakia into cancer, marked at first only by very slight and superficial hardening. (5) A white, warty growth or compound wart, neither broken nor ulcerated, and feeling at first as if it were fixed to the mucous membrane and quite superficial. Of fourteen cases operated on, three are dead, one of nephritis and heart disease eighteen months after operation and without recurrence, one of affection of the cervical glands but without recurrence, and one operated on for cancer of the right border of the tongue from cancer of the left border. The remaining eleven patients are alive and well at periods of from eight months to four and a quarter years.

Berliner klinische Wochenschrift, February 1, 8, and 15, 1909.

Iodophilia of the Leucocytes.—Stumpke corroborates the findings of Winkler according to whom iodophile substances are present in the pus and epithelial cells of gonorrheal discharge; the iodophile reaction is more marked in acute cases than in chronic gonorrheal affections. Stumpke believes that the iodophile phenomenon is a sign of some reaction in the protoplasm to new conditions and may appear and disappear in the cells with the different stages of the disease. These views were substantiated in the examination of the pus from chancroid ulcers which gave the iodophile reaction at the height of the development of the ulcer; the iodophile substances, however, diminished markedly with the beginning healing of the lesion. Syphilitic lesions appear to cause but little appearance of iodophile substances, that is, of glycogen, in the cells forming the lesion; mixed lesions on the other hand show the presence of cells with abundant glycogen content. In all affections of the skin accompanied by the production of vesicles and blisters the leucocytes of the serum filling these lesions proved to have abundant iodophilic substances. As the leucocytes of the blood were quite free from these substances, Stumpke concludes that the iodophile reaction

of the leucocytes is due to changes that take place at the site of the lesions and have some close relation to the character of the lesions.

Artificial Respiration.—Loewy and Meyer describe the method of artificial respiration proposed by Schäfer, in which the patient is placed on his abdomen and the respiration is carried on by the intermittent application of pressure to the sides and back of the thorax. In principle it is a method of artificial expiration, only the resiliency of the thorax causing the inspiration: it is therefore comparable to Howard's method in which compression was applied to the thorax while the patient was placed on his back. Loewy and Meyer think that the older method resulted in better ventilation of the lung, while still better is the Sylvester method that has been used almost universally before the Schäfer method was proposed. The Sylvester method leads to very active ventilation of the lungs and has the advantage of aiding inspiration as well as expiration. Such effect upon the inspiration is especially valuable as it helps the circulation of the blood as well as its aeration. Schäfer claims that one great advantage of his method consists in the ease with which the water that has entered the lungs of the patient is got rid of, when the artificial respiration is carried on with the patient in the prone position. However, the same results may be obtained by a momentary prone position or even by lifting the patient by his feet for a moment which allows the water to escape from the trachea and the larger bronchi, after which the Sylvester method may be continued. Moreover, there is danger not only from the water in the lungs but likewise from the water in the gullet and stomach; in the Schäfer method this water can easily be drawn into the air passages so that aspiration pneumonia is a very possible consequence. The dorsal position of the Sylvester method diminishes this danger very much. The danger of the tongue falling backward and asphyxiating the patient is, of course, a real one in the dorsal position, but it is easly prevented by pulling the tongue forward and holding it there during the resuscitation attempts. The Sylvester method is to be preferred, likewise, in other asphyxias in addition to those caused by drowning, for it has the one great advantage of providing better ventilation of the lungs than any other method.

Sacroiliac Tuberculosis.—Stieda says that tuberculosis of the sacroiliac joints is very hard to diagnose in the early stages because pain radiating to the back and to the limbs that is often present in this affection simulates simple neuralgic conditions. Tenderness over the joint is likewise hard to elicit and only the appearance of swelling, of an abscess, or, finally, of a tuberculous fistula confirms the diagnosis. Stieda calls attention to the fact that the so-called Trendelenburg phenomenon usually present in congenital dislocation of the hip is also very frequently present in the early stages of tuberculosis of the sacroiliac joint. This phenomenon consists in the sinking of the pelvis on the healthy side when the patient is compelled to lift the healthy leg while standing on the foot belonging to the affected side. This result is occasioned by the insufficiency of the gluteal muscles which normally keep the pelvis in a horizontal position when either limb is raised from the ground. In congenital dislocation such insufficiency is caused by real anatomical changes in the muscles, while in tuberculosis it is probably due to the fact that sufficient contractions of the muscles are prevented by the pain which would accompany the attempt to keep the pelvis in a horizontal position while the weight rests on the leg of the affected side. Diminution in the sinking of the pelvis on the healthy side is often observed with improvement in the disease and its grade may be used as a measure of such improvement.

Acute Serous Meningitis.—Axhausen says that the few cases of acute serous meningitis reported have usually been traced to edema occasioned by the presence of a neighboring infection; undoubted cases of such meningitis occurring quite independently of bacterial invasion have not been published, though several reports justify the supposition that such an affection may arise in connection with trauma without infection. Axhausen reports his case, that of a child struck by a stone in the left temporal region. The external wound was infected and fever appeared. As cerebral symptoms, including vomiting and stupor, were present, operation was decided upon, the possibility of purulent meningitis being suspected. The operation, however, showed that cerebrospinal fluid under great pressure had accumulated in the subdural space, this fluid being clear, free of leucocytes, and bacteriologically sterile. The temperature dropped to normal immediately after the operation and remained thus, while a very large amount of cerebrospinal fluid flowed from the wound. All at once, however, this discharge stopped, the temperature again rose to a high point, and general convulsions occurred. Another operation disclosed the repetition of the previous condition, cerebrospinal fluid under great pressure being liberated by a puncture of the dura. The course of the disease after this was uneventful, the child recovering completely. As infection of the meninges could be excluded because of the negative results of cytological and bacteriological study of the fluid and the rapid recovery of the child, Axhausen is inclined to believe that the case is that of a meningitis of serous nature caused by trauma to the skull.

Viceroptosis as a Constitutional Anomaly.—Albu has examined a great number of youthful individuals and of children in reference to the occurrence of viscerоptosis in them irrespective of the causes usually named in the possible etiology of the condition. He concludes that in the great majority of cases viscerоptosis is not an acquired condition, but is a congenital anomaly, which is simply latent so far as symptoms are concerned until some contributing factors increase the abnormalities of sensations and of function caused by the existence of ptosis. Viscerоptosis accompanies a certain form of the body characterized by excessive development in the long axis with imperfect development of the framework in the directions of breadth and depth. The extremities are usually elongated and thin, the face small, the throat long and thin, the thorax narrow and flat, and the abdomen narrow and long. The whole figure inclines to be very angular and among the bony irregularities accompanying this type of body we meet with stenosis of the upper thorax aperture, made so much of by Freund in the etiology of tuberculosis, and a freely floating tenth rib. The superficial coverings of the body show much diminished panniculus adiposus and a flaccid, weak musculature, especially evident in the abdomen. Albu thinks that the condition in question cannot be brought in connection with any temporary causes such as the wearing of tight corsets, lessened nutrition, etc. The congenital origin of this "habitus paraliticus" is well shown by the fact that it occurs among the many types of figures represented by painters and sculptors of older generations at a time when the conditions which are now looked upon as causative of the affection did not at all exist. This type of figure was the favorite one with Boticelli and lately it has been made almost a cult by men like Watts, Rosetti, Burne-Jones, and the latest impressionist and secessionist school of art. There is no question that the frequency of this congenital anomaly has been increased in the modern era by various abnormal conditions of life leading to illnutrition and to exhaustion of individuals whose children are then much more apt to show congenital deformities. The prophylaxis of viscerоptosis lies, therefore, not so much in measures directed toward individual cases, but in the improvement of general hygienic and social conditions, such improvement having most effect upon the physical and psychic development of future generations.

Münchener medizinische Wochenschrift, February 9 and 16, 1909.

Effect of Castration and of Hysterectomy.—Pankow says that the removal of the ovaries is followed by the well-known disturbances of vasomotor, psychic, and trophic nature. The first consist of attacks of dizziness, of increased perspiration, of various abnormal sensations in the eyes and ears, and of severe headaches. Psychic phenomena are rare and consist of weakness of memory and of frequent states of depression. Trophic disturbances are characterized by atrophy of the genital organs, which may be very rapid, and by great increase in the fat of the body. The sexual sphere is depressed quite markedly, so that the normal characteristics of a woman in this respect are either completely lost or may be perverted. These results have been attributed to the loss of internal secretion produced by the ovaries. On the other hand, hysterectomies have not at all been thought to produce any results comparable to castration and the possibility of such results does not usually enter the mind of the surgeon. Pankow has followed one hundred and fifty cases of hysterectomy in order to observe the phenomena resulting from this operation. The phenomena included under the term menstrual molimina never appeared after a hysterectomy unless they had

been present before the operation. If present, they usually continued for several months in undiminished intensity and then gradually diminished or disappeared completely. Only in very nervous individuals these complaints were sometimes more pronounced after the operation. Other phenomena, however, occurred in the intermenstrual periods and differed from those noted above as occurring after castration. No such atrophy of the external genitals ever took place as usually occurs after castration; great increase in the weight was noted but very rarely, except in women who were nearing the climacterium and would have gained weight at that period in the natural order of things; no such pronounced nervous disturbances as have been noted after castration were ever observed after simple hysterectomy; vasomotor disturbances frequently appeared in nervous patients or were intensified after the operation, but never reached the degree frequently seen after castration. Moreover, youthful individuals seemed to bear the operation of hysterectomy very much better than elderly women so far as sequelæ are concerned, which was quite different from the results in castration. In general, the phenomena noted after hysterectomy were so different from those noted after castration that they could not be explained by the atrophy of the ovaries occurring as a result of the removal of the uterus. Their intensity and character were such, moreover, that it is quite justifiable to assume that the uterus is not simply an organ of gestation, but is the source of an internal secretion as important for the general metabolism and life of the organism as is that attributed to the ovary.

Typhoid Infection of a Fetus.—Gaehtgens says that typhoid fever may exist as a pure septicemia without the presence of the characteristic lesions in the gastro-intestinal tract and in the mesenteric lymph nodes. Such infections have been found in newborn whose organism succumbs to the disease before local lesions arise. Gaehtgens reports a case of a woman who aborted during the fourth month of pregnancy while in the fourth week of typhoid. The organs of the fetus proved to contain typhoid bacilli in great numbers, although no bacilli were to be found in the placenta. The gastrointestinal tract did not show the typical lesions of typhoid. The author thinks that the infection of the fetus occurred either through a direct invasion of the chorionic villi by the bacilli or because of some hemorrhage destroying some portion of epithelium lining the villi. This must have occurred at the time when the bacilli were present in the blood of the mother, the absence of infection in the placenta showing that the bacilli disappeared from her blood at a later date. The observation shows once more the permeability of the placental tissue to pathogenic organisms as well as the power of the typhoid bacilli to produce death in the tender organism of a newborn child or of a fetus without giving rise to local lesions of the disease.

Wassermann's Reaction in Surgical Syphilis.—Baetzner has tried this reaction as an auxiliary diagnostic measure in over one hundred and twenty cases at Bier's clinic and has found it to be of great value in differential diagnosis of luetic affections from tuberculous or malignant disease. The serum reaction is a specific one and he has found that its positive result always showed the presence of syphilis. However, the reaction depends upon constitutional changes and not upon local manifestations of the disease, so that care must be taken not to look upon a positive reaction as surely signifying that a given local affection is syphilitic in character. Negative outcome of the reaction is to be given much less value than a positive result. He reports a score of cases in which the reaction was the deciding factor in making the diagnosis. The greater number of them were gummata of the soft parts in locations where malignant or benign tumors could not be easily excluded; some were cases showing all the characteristics of lupuoid affections, the serum reaction proving that a syphilitic process was present; frequently ulcers of the legs having the appearance of the usual lesions accompanying varicose veins, etc., were proved to be syphilitic in origin by the outcome of the reaction, and the therapeutic test fully confirmed the results of the reaction. Of especial use was the reaction in cases of joint disease where the differential diagnosis from tuberculosis affection is frequently very difficult. Baetzner concludes that the introduction of the reaction in question has very greatly simplified the recognition of syphilis as the cause of many obscure lesions of the soft parts, bones, and joints.

Deutsche medizinische Wochenschrift, February 4, 1909.

Operative Treatment of Stomach Carcinoma.—Kuttner says that two things may be considered as proved: that carcinoma of the stomach may be cured completely by a timely radical operation, and that in many cases where the life of the patient cannot be saved his comfort can be materially increased by a surgical procedure. It is therefore the plain duty of the internists to send their cancer patients to the surgeons as early as possible so that the patient may be given all possible chances of recovery from his disease. That this custom is not equally observed in all lands may be concluded from the statistics of the operations for cancer; the very good results obtained by some operators such as Kocher are due to his technique as well as to the fact that a great number of his patients are referred to him in the early stages of the disease. The best chances of radical cure are present in cases where the tumor is situated at the pylorus or at the lower curvature of the stomach; tumors of the greater curvature and of the posterior or anterior walls of the stomach are seldom operated upon early enough to be totally removed, while tumors of the cardia form a hopeless condition in the great majority of the cases. In addition to the situation of the tumor the following points are of most importance in deciding the chances offered by an operation: the state of the nutrition of the patient, the amount of stomach tissue involved, the adhesions to other organs, and finally the presence of metastases. The state of nutrition is best judged by a complete examination of the blood, and operation is not advisable where the hemoglobin is very low. The opinions as to the size of tumor permitting an operation are divided, but many operators claim that a palpable tumor is always too late for surgical interference. This, however, is not correct, Kuttner having had cases in which a palpable tumor was removed and the patient recovered. The presence of adhesions often makes the tumor inoperable as the adhesions are usually due to infiltration of the surrounding tissue: it must be remembered, too, that the adhesions are much more extensive and frequent than is shown by the external examination. The presence of metastases in the lymph glands is not thought by some to speak against the success of the operation, for the possibility of the cancer cells dying in the lymph nodes has not been disproved. As far as gastroenterostomy is concerned, Kuttner always tries to limit the indications for it as in most cases removal of the tumor or resection of a portion of the stomach is the more promising procedure. Kuttner defends the propriety of exploratory operations if any doubt exists as to the condition of the stomach. In cases of chronic ulcer of the stomach that are most frequently taken for carcinoma this procedure may be followed by extirpation of the ulcer so that the diagnosis is not the only result of the exploratory incision. Kuttner concludes with a plea to strike the right note between the pessimism of some and the optimism of other surgeons, and to operate in all cases where the least chance of saving the patient's life or increasing his comfort is present.

Operative Interventions Upon the Stomach and the Modifications of the Intestinal Chemismus.—Betagli has made experiments on gastroenterostomized animals as to the condition of the intestinal chemismus. He produced a stenosis, or an occlusion, of the pylorus. He then examined the function of the pancreas and the secretory action of the duodenal mucosa. When the pylorus is left pervious all the functions go on normally. But when the passage of the acid chyme into the duodenum is prevented there are modifications of the normal condition. These cause dyspeptic symptoms and probably assist in causing a return of the original disease process or an alteration of the anatomo-pathological condition of the organ.—*La Riforma Medica.*

Action of the Mucosa of the Bladder on Microorganisms.—V. De Bonis and A. Pane have experimented on animals to ascertain whether the mucosa of the bladder has any bactericidal effect on bacteria introduced into the bladder. They conclude that there is no bactericidal effect produced by the mucosa of the bladder. All the bacteria that were used in their experiments increased in numbers progressively, and their colonies grew larger. The colonies examined microscopically were entirely typical in form. While the urine flows freely through the bladder it presents a medium in which the germs grow normally. There is very little absorption of the bladder contents, and the increase in growth of the colonies is not due to the concentration of the urine, but to a true multiplication of the organisms.—*Giornale Internazionale delle Scienze Mediche.*

Book Reviews.

The Campaign Against Tuberculosis in the United States, Including a Directory of Institutions Dealing with Tuberculosis in the United States and Canada, Compiled Under the Direction of the National Association for the Study and Prevention of Tuberculosis. By Philip P. Jacobs. New York: Charities Publication Committee, 105 East Twenty-second Street, 1908.

This most useful publication which is mainly a directory of sanatoria, hospitals, clinics, dispensaries, "classes," etc., for the treatment of tuberculosis, and also of associations and committees for the study of the disease in the United States and Canada, is published for the Russell Sage Foundation. There is first a list of the sanatoria, hospitals, and day-camps for the treatment of tuberculosis, alphabetically arranged; then a similar list of hospitals for the insane and of penal institutions making special provisions for their tuberculous inmates; following are lists of dispensaries and clinics for the special treatment of tuberculosis, and tuberculosis classes; then a list of the associations and committees for the study and prevention of tuberculosis, and specimen constitutions and by-laws of typical associations of this sort. A chapter follows on legislation affecting tuberculosis in the United States, including an outline of the activities of State and local boards of health; and this is succeeded by a section giving typical laws regarding notification and sanatoria, antispitting laws, and municipal ordinances. An appendix contains a chart and tables showing the growth of the antituberculosis movement. The book is indispensable to all interested in the campaign against tuberculosis, and will be found extremely useful by physicians who may be consulted regarding the various sanatoria and other places for the treatment of the tuberculous.

Studies in Puncture Fluids. A Contribution to Clinical Pathology. By O. C. Gruner, M.B. (Lond.); Clinical Pathologist at the General Infirmary, Leeds; Late Hon. Pathologist to the Leeds Public Dispensary. London: H. K. Lewis; Philadelphia: P. Blakiston's Son & Co., 1908.

The progress made by clinical pathology in recent times is shown by the appearance of numerous monographs dealing with special features of the subject. The volume before us is such a monograph and combines a presentation of our scientific knowledge of normal and abnormal fluids that can be obtained from the cavities of the human body, with practical application of this knowledge for purposes of diagnosis. The general part of the book deals with the chemical and physicochemical methods employed in the examination of puncture fluids; every detail of the technique to be employed is noticed, which makes the book very valuable for purposes of reference. The special chapters consider the characteristics of pleural and peritoneal fluids, of joint effusions, of the cerebrospinal fluid and of the fluids obtainable from cysts. Cytological findings are likewise noted, and the literature of the subject is appended. Dr. Gruner's work will be appreciated by every pathologist, for the book will undoubtedly save many a weary search through recent literature for scattered accounts of technique and findings in the examination of puncture fluids; his judicious statements of the interpretation of such findings are especially to be commended; they show the futility of seeing in any one special method of examination the only path to be followed in diagnosing disease and at the same time serve to place a correct valuation upon the service that a competent examination of the puncture fluids can furnish as a valuable means in aiding such diagnosis. The book is heartily commended to the attention of laboratories, libraries, and individual workers in clinical pathology.

Tuberculosis in Infancy and Childhood; Its Pathology, Prevention and Treatment. By various writers. Edited by T. N. Kelynack, M.D., Member of the Royal College of Physicians of London; Hon. Physician in the Infants' Hospital, Westminster; Medical Adviser to the National Children's Home and Orphanage; Hon. Physician to Mount Vernon Hospital for Consumption and Diseases of the Chest; Member of Hon. Medical Consulting Staff of the National Association for the Feeble-minded. New York: William Wood & Company, 1908.

The present work, consisting as it does of a very full symposium on tuberculosis in early life, is an elaboration and expansion of a series of articles which appeared on the subject in the July, 1907, number of the *British Journal of Tuberculosis*. It is quite unique in its arrangement and is a really valuable addition to the voluminous literature on tuberculosis. Thirty-eight authors, well known in their respective branches, have contributed each a short essay to this work. The papers are all of them brief and to the point, and are evidently written with the principal object of bringing the sum of our knowledge on this subject, in as few words as possible, down to the present hour. The opening chapter by the editor discusses the problem of prenatal, infantile, and childhood tuberculosis, showing very graphically the prevalence of tuberculosis in early life, its frequency among school children, the early development of predisposition, and various pathological considerations. The closing chapter, also by the editor, on the "Prevention and Arrest of Tuberculosis in Infancy and Childhood" summarises our knowledge of prophylaxis and treatment of the disease in the earlier years of life. Among the more interesting chapters, which are especially well conceived, may be mentioned those on "Pulmonary Tuberculosis in Infancy and Early Childhood," by Dr. L. Emmett Holt; "Tuberculosis of the Urinary Tract and Genital Organs in Early Life," by David Newman; "Tuberculosis Among Children in Scotland," by R. W. Philip; "Tuberculosis Among Children in France," by Calmette and Breton; "Exercise in the Management of Tuberculous and Tuberculously Predisposed Children," by Harry Campbell; "The Hygiene of the Nursery in Relation to Tuberculosis," by Mary D. Scharlieb, and "School Hygiene and Medical Inspection in Relation to Tuberculosis in Children," by W. Leslie Mackenzie and J. Hally Meikle. As might be expected, most of the contributors to this symposium are Englishmen, but there is a good representation from the United States, France, Germany, Switzerland, Sweden, and Norway. The work is indexed both for authors and subjects.

Clinical Bacteriology and Hæmatology for Beginners. By W. D'Este Emery, M.D., B.Sc. (Lond.); Clinical Pathologist to King's College Hospital and Pathologist to the Children's Hospital, Paddington Green; Formerly Assistant Bacteriologist to the Royal College of Physicians and Surgeons, and Sometime Lecturer on Pathology and Bacteriology in the University of Birmingham. Third Edition. Philadelphia: P. Blakiston's Sons & Co., 1908.

Dr. Emery's handbook appears in the third edition with only a few changes. These include a brief account of the preparation of bacterial vaccines, some new methods of taking blood cultures by means of all-glass syringes, full description of the technique of spinal puncture as a diagnostic procedure, etc., etc. The book is a concise account of the apparatus and processes of bacteriology, of the methods used in the laboratory diagnosis of certain diseases, of the technical procedures to be followed in collecting material for bacteriological examination and for the examination of the blood. A short account of the newer cytodiagnostic methods is also given. The book is written very clearly and affords a safe guide for the student and the practitioner. Though meant for a beginner in hematology and bacteriology, it should meet the needs of most practitioners of medicine not engaged in extensive bacteriological and hematological work.

Burdett's Hospitals and Charities, 1908; Being the Year Book of Philanthropy, and the Hospital Annual, Containing a Review of the Position and Requirements, and Chapters on the Management, Revenue, and Cost of the Charities; an Exhaustive Record of Hospital Work for the Year; It Will Also Be Found to Be the Most Useful and Reliable Guide to British, American, and Colonial Hospitals and Asylums, Medical Schools and Colleges, Nursing and Convalescent Institutions, Consumption Sanatoria, Religious and Benevolent Institutions and Dispensaries. By Sir Henry Burdett, K.C.B., Author of "Hospitals and Asylums of the World"; "Hospitals and the State"; "Pay Hospitals of the World"; "Cottage Hospitals: General, Fever, and Convalescent"; "Burdett's Official Nursing Directory"; "The Nursing Profession"; "Helps in Sickness and to Health"; "The Relative Mortality of Large and Small Hospitals," and Editor of "The Hospital." London: The Scientific Press, Limited, 1908.

The very comprehensive subtitle of this most useful work of reference explains fully its character and the scope of its contents. This country does not receive as much attention as we wish it might, but the editor explains this by the failure, through press of work, of his American collaborator to contribute a chapter on hospital affairs here. The editor promises "to give more space in future editions to the important work and developments which the American people have undertaken and are pursuing with so much zealous energy." Chapter XII does, however, contain a good deal of practical and useful information relating to American and Colonial hospitals in a form which cannot fail to be of value and interest to all intelligent workers in the field of charity

Society Reports.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Annual Meeting, Held January 18, 1909.

The President, Dr. Robert T. Morris, in the Chair.

A New Method of Recognizing the Presence and Location of an Ulcer of the Stomach.—Dr. Max Einhorn referred to the difficulty of making a positive diagnosis in ulcer of the stomach, where one frequently had to rely upon the presence of blood. Some months ago, while treating a case of suspected gastric ulcer, he introduced a duodenal bucket, which passed through the pylorus into the duodenum, and upon its withdrawal the following morning the white thread to which it was attached was found to be blood-stained at a point corresponding to the pyloric orifice. This led to the idea of the present method, which consisted, essentially, in introducing the duodenal bucket and leaving it over night in the digestive tract. After its withdrawal, the thread was inspected. If there was distinct impregnation of blood, it indicated the presence of ulcer. The thread test was applicable only if the ulcer was situated along the esophagus, cardia, lesser curvature of the stomach, pylores, or duodenum. For ulcers in other regions of the stomach the following procedure could be applied: A thin rubber bulb with a rubber tube attachment, through which it could be inflated, and inclosed in a white linen-mesh bag, was introduced into the stomach and then inflated and allowed to remain in contact with the stomach walls for thirty minutes. Then it was deflated and withdrawn. After its withdrawal it was again inflated and allowed to dry. The linen-mesh bag surrounding the rubber bulb would then distinctly show traces of blood or ulcerated tissue with which it had come in contact in the stomach. In one of the cases in which he had resorted to this expedient, Dr. Einhorn said, the presence of an ulcer on the base of a cancer was discovered; in others there were evidences of ulceration and blood. The location of the ulcer could often be ascertained by this method.

Some Serious Lapses in Administrative Hygiene.—By Dr. Homer Wakefield. (See page 220.)

Dr. Charles E. North said he agreed entirely with what Dr. Wakefield had said in regard to undrawn cold storage poultry. With reference to cold storage eggs, the speaker referred to the method of keeping broken eggs in liquid form in large cans. These were not evaporated, but simply broken, and were largely used by bakers in making cake. Under proper restrictions, this was not a bad method of preserving eggs for baking purposes, and was certainly better than allowing the bakers to use cracked and discarded eggs, which was not infrequently done, the bakers depending on the heat of the oven to get rid of the odor and taste. Whether this also destroyed the toxins of bad eggs the speaker was unable to say. He said he agreed with Dr. Wakefield that rotten ensilage should not be fed to cattle. The more reputable dairies fed their cattle with good ensilage. The question arose whether toxins were ever produced in milk before it soured. As to pasteurized milk, he had been unable to kill guinea pigs by injecting them with milk thus treated. Probably the heat destroyed most of the toxins, or else the bacteria that remained after pasteurization did not produce toxins.

Dr. J. Herman Branth said the climax of commercial greed had been shown in the process of storing undrawn poultry by the freezing process, and then selling this, manure and all, as food. He had been told that many hunters drew partridge, quail, rabbits, squirrels, etc., at once, and fed the dogs on the entrails, which they believed improved the hunting quality of the dogs, while they claimed that game thus drawn possessed the finest flavor. Others leaned towards the so-called French style, where the gourmand had cultivated the "gamey" or "high" taste which the early stages of putrefaction furnished. The French, for instance, cooked or baked reed birds with the entrails, claiming that the contents of the intestine, owing to the food of the bird, imparted a certain "nutty" taste. Then, Dr. Branth asked, why not cook squirrels the same way? Or, better still, take out the entrails, cook these and discard the carcass. This was said only to show contrast and absurdity. The speaker then quoted from Dr. Harvey W. Wiley, U. S. Government Chemist, who testified before the Congressional Committee on Agriculture in Washington to the effect that while cold storage for a short time was a good thing for some foods, it was positively harmful for others, and that he was carrying on certain experiments in order to learn how long certain articles of food might safely be kept. In the manner of our feeding, Dr. Branth said, we were getting too far away from nature. Food preserved for a long time must deteriorate. The best we could do was to preserve some foods until the season for their production arrived again, but let such a process of preservation be clean, like the steps of an aseptic operation, a process in which the entrails of animals or of birds had no place. The sale of undrawn poultry ought to be prohibited. From a Jewish rabbi he had learned that Jews dressed the fowl on the day of killing and that they did not eat meat kept for a long time. Our Board of Health took great pains to inspect every cow stable and dairy, so that the milk supply of the city might be wholesome; why not urge a movement that similar attention be given to poultry farms?

Dr. Henry G. Piffard said that some years ago the Board of Health declared that undrawn poultry was more wholesome and less liable to bacterial infection than were fowls that had been opened and drawn. That was one of the foolish regulations adopted by our health authorities. Dr. Wakefield, in his paper, had referred to ensilage containing butyric and lactic acid, which was known as sour ensilage, but he had said nothing about that in which there was not an acid but an alcoholic fermentation; this was the kind that many dairymen preferred to use and many cattle preferred to eat. In speaking of raw fresh fish, which was a recognized article of diet among the Japanese and certain other nations, the speaker thought that in some respects it was less objectionable than raw oysters. Referring to the use of tuberculin, Dr. Piffard said that about seventeen years ago he wrote a paper objecting strongly to its use in human beings. Personally, he believed that tuberculin had seen its day, and that it would soon be superseded by other methods of detecting tuberculosis. One of these methods, recently devised by a Japanese investigator, was to obtain blood serum or blister serum from a suspected subject; this was injected into a rabbit and the animal was then injected with tuberculin and its effects noted. Still another method was now being experimented with by Dr. Rosenberger of the Jefferson Medical College. Briefly, this was as follows: He drew five c.c. of blood from the median cephalic vein; this was put into a test-tube which already contained a solution of sodium citrate and salt. After twenty-four hours' sedimentation the serum was removed with a pipette, and the thick sediment was spread over a slide. The hemoglobin was washed out and the slide stained with carbol-fuchsin, followed by acid alcohol. In this manner Dr. Rosenberger claimed that he had been able to find the tubercle bacilli in over one hundred cases of clinically recognized tuberculosis, and they had also been found in a number of other cases in which tuberculosis had not been recognized. This method could be applied not only to pulmonary cases, but also to glandular and joint cases. Many years ago, Dr. Piffard said, Jonathan Hutchinson declared that leprosy

was due to eating fish, which were sometimes tuberculous, some species more so than others. In Hawaii it had been found that many of the lepers responded to the tuberculin test, and the lepra bacillus was practically indistinguishable from the tubercle bacillus.

Dr. Achilles Rose said that Küchenmeister, our best authority on helminthiasis, found that the frequency of tapeworm among the Swedish people could be traced to their custom of eating raw salmon.

The discussion was continued by Dr. Branth and closed by Dr. Wakefield.

Demonstration of Models Illustrating Certain Phases of Syphilis.—Dr. William S. Gottheil showed colored wax models, illustrating various lesions of syphilis, including initial lesions of the lip and elsewhere, various forms of scleroses, rupia syphilitica, dactylitis syphilitica, gumma of the penis, tertiary ulceration of the auricle, and one case showing eleven initial lesions on the penis of a man who contracted syphilis during the outbreak of a crop of herpes præputialis. He also showed an interesting model of a bullous iodide eruption of the hemorrhagic type.

The Serum Reaction (Wassermann's Reaction) in Syphilis. The Principles and Technique of the Reaction.—By Dr. Howard Fox. (See page 421.)

The Practical Application of the Reaction and Its Value in the Diagnosis and Treatment of Syphilis.—Dr. Boleslaw Lapowski, discussing this phase of the subject, said the reaction was not a specific one in the bacteriological sense, in that it was not directly due to the products of syphilis, but it might be considered as a clinically specific sign of syphilis, owing to the great number of syphilitic cases where the reaction was positive, reaching the average of 90 per cent. In a very small number of nonsyphilitic cases, such as malaria and leprosy, the reaction was also positive while no syphilis was present. The positive reaction indicated only the presence of syphilis in the organism, but not necessarily the focus of the syphilitic disease. In cases of doubtful diagnosis the positive reaction was of great importance, especially for the surgeon. Many operations would be avoided, and active specific treatment substituted. A positive diagnosis meant syphilis, but a negative one could not always be considered as proof of absent or cured syphilis, as a negative reaction might occur in cases with manifest syphilis. In shaping our plan of treatment, the reaction was not entitled to any more weight than was given to any other clinical symptom of syphilis. We should not be influenced by the reaction alone, but by other considerations, such as the age of infection, the toleration of the patient to mercury, etc. The value of the reaction in the treatment was limited to those stages of syphilis in which we formerly abstained from treatment because, not being able to demonstrate the activity of the syphilitic virus, we acted upon the supposition that the syphilis was either inactive or cured.

Dr. H. Noguchi of the Rockefeller Institute for Pathological Research demonstrated briefly a reaction evolved by him during some experimentation with the various albumin reactions in the spinal fluids of general paralysis and other disorders. This was obtained as follows: 0.1 c.c of the spinal fluid to be tested was placed in a test tube whose diameter was 1 cm. or less. To this was added 0.5 c.c. of a 10 per cent. solution of butyric acid. The tube was now heated until the fluid was bubbling, and while still hot 0.1 c.c. of a normal (4 per cent.) solution of sodium hydrate was added. In nearly all spinal fluids an opalescence or cloud occurred, but in the spinal fluid of general paralysis the cloud soon separated into a definite flocculence which was characteristic The flocculence usually appeared in a few moments—rarely requiring more than twenty minutes. The reaction shown by Dr. Noguchi had the advantage of being positive in a quantity of 0.1 c.c. or less, and of being a qualitative as well as a quantitative test. What the flocculence might mean was not known, but it might consist of some globulin fraction which was found only in syphilitic or metasyphilitic disorders of the nervous system. That the reaction was not entirely quantitative, Dr. Noguchi said, was shown by the fact that many fluids from nonparalytic cases gave much richer clouds than those from paresis, but in such cases the clouds did not flocculate.

Dr. Charles Wood McMurtry said that while these newer methods, especially that of Noguchi, were exceedingly interesting, he thought that for the sake of clinical accuracy we should confine ourselves to the Wassermann reaction—the complement fixation test as laid down by Wassermann-Neisser-Bruck. The speaker suggested that obstetricians should carry test-tubes in their obstetric bags and obtain some of the blood that was lost in delivery, to be utilized for the purpose of securing blood serum for the Wassermann test. This would lead to the detection and treatment of many cases of latent syphilis in apparently healthy women and babies. In abortions, miscarriages, premature deliveries, or the birth of dead fetus, the test would prove of great value. Another suggestion he made was the various health boards should add the Wassermann test to their facilities for diagnosis, so that even the more modest practitioners could avail themselves of this test in treating the poorer classes of patients. Syphilis was a highly dangerous, infectious disease, and as such merited the attention of our health authorities.

Dr. Edward D. Fisher said that his experience with serum reactions in syphilis had been limited to the report of such cases as had come under his observation and not from personal investigation. In the majority of cases of general paresis, the diagnosis could be made from the clinical symptoms; it was in the doubtful cases that the value of these reactions would be tested, and until a greater number of cases had been recorded, and a greater number of control cases had been examined, the true diagnostic value of the Wassermann reaction was still open to question. It was well known that cancer, tuberculosis, typhoid fever, and multiple neuritis had shown the Wassermann reaction. Dr. Fisher said he was very much in favor of experimental work in this direction, but was opposed to optimism when further investigation was still necessary. He asked whether the reaction was present in cases of syphilis after the patients had been subjected to energetic antisyphilitic treatment. He was not aware that any observations had been made covering that point.

Dr. James Pedersen, quoting Dr. Francis Carter Wood, said that such tests as the Wassermann usually passed through four stages, namely, the stage of universal acceptation, the stage of doubt, the stage of almost total neglect, and, finally, the stage of equilibrium—when its true value had been determined by much testing and research. He thought Dr. Lapowski's paper stated admirably the present status of the test under discussion, namely, that it was, and probably always would be, a laboratory aid to the usual clinical facts on which a diagnosis must be based The test should not be regarded as pathognomonic

Dr. B. Sachs said that he had personally applied the Wassermann test in about one hundred cases, and eighty of these he had full control of. While the technique of the method was not easy, it could be acquired by a little patient study, and he advised as many practitioners as possible to take the time and trouble to do this. In every hospital and in every clinic there should be at least one man—preferably one of the younger members of the staff—who was fitted to make these examinations. The value of the test was admitted in all the clinics abroad, and it was a distinct help in the recognition of late syphilitic manifestations. In one case of supposed amyotrophic lateral sclerosis coming under the speaker's observation some doubt was raised as to the correctness of the diagnosis,

and both the blood and cerebrospinal fluid gave a positive Wassermann reaction. The subsequent autopsy proved the case to be one of diffuse cerebrospinal lues. In several cases of supposed disseminated sclerosis the test was employed and showed them to be cases of multiple cerebrospinal syphilis. In one case of transitory paraplegic attacks with sudden unilateral blindness, the patient was referred to an ophthalmologist, who found nothing in the fundus of that eye and regarded it as a retrobulbar neuritis. A syphilitic lesion was suspected, and a positive Wassermann reaction was obtained. Dr. Sachs, in reply to Dr. Fisher's question, said he thought the reaction was modified by energetic specific treatment, and he had noted that under such conditions it became less and less positive.

NEW YORK ACADEMY OF MEDICINE.

Regular Meeting, Held February 18, 1909.

THE PRESIDENT, DR. JOHN A. WYETH, IN THE CHAIR.

Animal Experimentation.—Dr. JAMES PETER WARBASSE read this paper. Animal experimentation, from the medical standpoint, meant the examination of living animals for the purpose of discovering and observing the functions of organs; determining the effects of operations, injuries, or diseases; ascertaining the reaction of the body to medicinal substances; making diagnoses by injecting suspected materials; discovering the disease-carrying nature of animals; manufacturing prophylactic, curative, or diagnostic sera; discovering antidotal remedies; practising surgical operations; experimenting with the view of finding means for accomplishing the extermination of harmful animals; and studying the nature of diseases which were common to both man and animals. The animals used in these experiments represented practically all animals. The most commonly employed were fishes, mosquitos, mice, rats, guinea-pigs, chickens, dogs, cows, horses, monkeys, and men. A comparatively small amount of experimentation involved operations upon animals, and these operations were practically all performed with the animal under the influence of an anesthetic. In 1907 in England 73,000 experiments upon animals were made, and 96.5 per cent. of these were inoculations; in the remaining 3.5 per cent. anesthetics were used. At the present time not more than one experiment in 100,000 was actually painful to the animal. Pain appreciation was dependent upon the mental development of the individual, and primitive people had an insensitiveness to pain which was beyond comprehension. Their self-mutilations were made possible not so much by bravery as by this low degree of pain sense. Do animal experimenters inflict unnecessary and wanton pain? If an operation had been done that would have a painful result, the animal was usually killed while unconscious. In the physiological laboratory the condition of dogs after operation was not unlike that of their human brethren; they were comfortable and happy, playing about their kennels, and enjoying better care than had before been their lot. Of all the destruction of animals which was now in progress on the face of this earth, he said, he knew of none which was giving greater returns to humanity in contributing to man's health, culture, and happiness, animal for animal, than that practised in the interest of advancing the medical and biological sciences. Every department of physiology owed its best development to animal experimentation. Typhoid fever, tuberculosis, the plague, cholera, diphtheria, yellow fever, malaria, cerebrospinal meningitis, syphilis, smallpox, myxedema, cretinism, and snake-bite were but a few of the maladies that had been studied by animal experimentation and, in consequence, rendered more amenable to treatment. There were a large number of diseases, peculiar to the animals which were useful to man, the natures of which had been discovered and the prevention and cure of which had been accomplished by experiments upon living animals. Professor Huxley said of Pasteur that his discoveries in money value alone had been sufficient to make good the war indemnity of one thousand million dollars, paid by France to Germany. The conquest of diphtheria was due to Pasteur more than to any other man. His experiments were carried on with guinea-pigs, rabbits, and dogs. Regarding the dog as a public menace, the City of New York in one month last year caused 6,000 to be killed. London killed by suffocation more than 30,000 dogs annually. Boston killed 3,500 dogs and 14,000 cats annually. It was just such stray animals as these that were used to increase biological knowledge and help humanity. Which was the better way for them to die, in contributing to man's relief from the scourge of disease, or by being suffocated in closed chambers filled with carbonic acid gas?

It should be remembered that animal experimentation did not mean animal cruelty. The number of experiments in which painful operations without anesthesia were practised was comparatively small. The reference to "cutting up" of living animals, popularly made by those unfortunate persons who spoke in ignorance of these things, was as absurd as it was malicious. The dignity of this subject would not permit the speaker to pay his respects to those deluded persons who opposed these investigations. Most were prompted by ignorance. The psychology of their opposition was well understood by students of sociology and by students of the derangements of the nervous system. There was no great work for human betterment which had not had its "anti" movement. The real cruelty to animals was not in the hands of those who were making animal studies. All of the experiments upon vertebrate animals of every character, with or without anesthesia, everywhere in the world, were inconsiderable compared with the cruelties of the huntsmen and of the drivers and trainers of animals. Animals were ruthlessly slain and dragged away from their young, to clothe our bodies in the skins of wild beasts like prehistoric savages; they added their plumage to the abounding glory of women's hats; they were stripped of their skins to cover our feet and hands; we ate their flesh. Where one animal was mercifully destroyed for the sake of science, tens of thousands were brutally slaughtered for man's vanity. When the question of vivisection was receiving legislative consideration in England thirty-five years ago, Huxley declared that he trusted to the fox-hunting instincts of the House of Commons rather than to any real interest in science in that body for a moderate treatment of the question. As an evidence of unenlightened sentimentality in England, they now had a law which made no objection to a boy trolling for fish or setting lines baited with live frogs, but laid the teacher of the boy open to imprisonment and fine if he used the same animal to demonstrate to the boy the circulation of the blood in the web of its foot without inflicting any pain, and only subjecting the animal to the annoyance of being wrapped and restrained in a wet cloth. Now English scientists were going to France and Germany to carry on their studies.

SECTION ON SURGERY

Stated Meeting, Held January 8, 1909.

DR. ELLSWORTH ELIOT IN THE CHAIR.

Fracture of the Os Magnum.—Dr. EDWARD W. PETERSON presented this case. He said that in the December number of the *Annals of Surgery* Dr. A. H. Harrigan of New York reported cases of fracture of the os magnum

and, in a search through the literature, he had succeeded in finding but five authentic cases of fracture of this bone. Therefore, he thought it might be of interest to show another case. The patient was a man, fifty-eight years old, who tripped and fell upon the extended hand. An examination two days later showed the dorsum of the hand swollen and a painful joint. There was a particularly painful and tender point over the head of the os magnum. Upon manipulation there was a distinct bony crepitus. Dr. Peterson showed radiographs taken of the joint. He presented the patient because of the rarity of the injury sustained. It might have been mistaken for a sprain. To-day there was proper function of the joint.

Dr. CONNELL took exception to the *x*-ray findings shown in the radiograph presented by Dr. Peterson, and said that the line demonstrated as fracture of the os magnum was quite common in pictures of the wrist. This was caused by an overlapping of the os magnum by the posterior margin of the scaphoid.

Dr. SAMUEL LLOYD regretted that a picture of the normal wrist was not shown. The plate shown by Dr. Peterson should be considered with the clinical symptoms. There was, in his opinion, no doubt as to the diagnosis of fracture of the os magnum. There was a distinct crepitus produced when this bone was seized with the fingers.

Dr. PETERSON said that the diagnosis of fracture of the os magnum was made before the patient was sent to be *x*-rayed.

Direct Blood Transfusion for Gastric Hemorrhage.—Dr. CHARLES H. PECK presented a woman, twenty-eight years old, who was admitted to the hospital July 1 with a history of having had ten severe hemorrhages from the stomach in the seven days preceding her admission. She had indigestion and epigastric pain, and was greatly exsanguinated. Operation was deferred because of her critical condition, and in the hope that the hemorrhages would cease. The day after admission she passed a large quantity of blood in the stools, showing that fresh bleeding had occurred. It was then decided to do a direct transfusion of blood, with her husband as the donor. The flow was maintained for thirty-five minutes, with an immediate improvement in the patient. Before the transfusion was begun the hemoglobin was 30 per cent., the red cells 990,000, and the blood pressure 105. Immediately after the transfusion the hemoglobin was 60 per cent., the red cells numbered 2,400,000 and the blood pressure was 144. On July 6 the pallor was seen to be increasing, and she had a slight icteric tinge. On July 7 the pallor still increased, the hemoglobin was again 30 per cent., the red cells 1,040,000, and it was then that they decided upon doing a gastroenterostomy. This was done with the posterior suture and no loop method. There were no macroscopical evidences of ulcer found. Following the operation she was able to take nourishment and medication well. Up to July 12 the red cells numbered about 1,000,000. From then on the convalescence was uneventful. She left the hospital twenty-four days after the gastroenterostomy. This case was of interest because of the immediate benefit that followed the direct blood transfusion. Just what part the operation of gastroenterostomy had to play in her recovery he could not say.

Sarcoma of the Calf of the Leg.—Dr. JOHN F. ERDMANN presented this case. The patient was a dentist, twenty-two years old. His illness began two years before his visit to Dr. Erdmann's office. The right calf was swollen and larger than the left. It gradually increased in size, becoming hard and fixed. It was semifluctuant, and the size of a cocoanut. It presented the appearance of a sarcoma. The circumference was nineteen and a half inches. On August 6, Dr. Erdmann excised the tumor, taking away with it the gastrocnemius muscle, as well as everything that looked at all suspicious. The man made a perfect recovery, and now had no difficulty in walking or standing during the long periods required by his occupation as a dentist. He could raise the body while standing on the affected foot alone.

Foreign Body in Intestines.—Dr. W. S. SCHLEY presented a boy whom he had seen at the dispensary that same afternoon. At four o'clock the day previous, while attempting to demonstrate his ability to pass into his throat a stick, he met with this accident. The stick of wood, four inches long and about the thickness of the finger, was grasped by the muscles of the pharynx and passed to the esophagus and from there to the stomach and intestines. This foreign body was first felt in the intestines about the level of the umbilicus and, upon examination, was later felt in the jejunum. Dr. Schley thought that it would be passed in the natural way and operation would not be required.

The Operation of Direct Blood Transfusion, with the Description of a Simple Method.—Dr. JOHN A. HARTWELL read this paper, which dealt with the technique of direct transfusion and its dangers, with the means of guarding against the latter. The improved method of end to end suture of the donor's artery and the recipient's vein, as practised by Carrel, gave perfect results in animals, and had been used with success in the human subject. It was an operation, however, of very difficult execution, and in the hands of many surgeons had failed because of the formation of a clot. Its success depended upon the most rigid asepsis, and a most careful attention to every detail. His own experiences, as well as the experiences of others, led Dr. Hartwell to devise some simpler and more certain method for the transfusion of blood. The radial artery of the donor was dissected out for a distance of two inches, or more if convenient, under cocaine anesthesia. The small branches were isolated and tied, and a ligature thrown around the distal end, but not tied. The wound was covered with a moist, warm pad. An accessible vein in the forearm of the recipient, below the bend of the elbow, was exposed for the same length. If possible, a small tributary was dissected free for an inch at some point central to the proposed site of anastomosis. This was loosely clamped at its distal end. A ligature was then tied around the distal end of the main vein, and the vein divided just central to it. If needed, a light obstructing clamp was put on the vein higher up, but it was not always required. The adventitia was carefully stripped from the cut end of the vein, and three sutures of fine silk impregnated with vaseline were passed through the media and intima at a distance of 120° on the cut circumference of the vein. The wound was then covered with a moist, warm pad. The artery ligature was then tied, an obstructing clamp was gently placed on its exposed central part, and the artery divided with sharp fine scissors just above the ligature. The adventitia was removed from the cut end, and then a small roll of it was slid upward along the artery for a distance of an inch or more, and left attached. Through this a silk ligature was passed, tied, and cut about one-half an inch long. The artery was then immersed in liquid vaseline, and by means of a small forceps gently grasping it at about one inch from its cut end, was passed directly into the mouth of the vein, which was held open with the three sutures. The arterial wall was sufficiently rigid to make this step very easy. One, or if need be, two, of the venous sutures were then clamped either to the suture in the adventitia, or to a radial branch, in order to prevent the separation of the two vessels, and the excess of venous circumference clamped so as to snugly hold the artery, but not to constrict it. The obstructing clamps were then removed, and the flow proceeded. The dangers to the recipient attending the operation fell under four heads, viz., a hemolytic action of one blood on the other, the entrance of blood

or air emboli into the circulation, the use of a donor who had some undemonstrable communicable blood disease, and over distention of an enfeebled right heart. Dr. Hartwell offered the following conclusions: (1) The operation of direct blood transfusion as practised with suture and cannula showed a large percentage of unsatisfactory results. It required special instruments and unusual skill for its successful execution. (2) The direct entrance of the artery into the vein had proved a simpler and more satisfactory method in a large series of experiments and in one clinical case. (3) At present they had no means of obtaining accurate knowledge of the quantity of blood entering the vein. The changes in hemoglobin, red cell count, pulse rate, and blood pressure must all be given weight in estimating this quantity. Actual weighing of the donor might solve the problem. (4) The operation was not without danger from hemolysis, embolus, or over distention of the right heart, but with proper care these should be avoidable. All the animals used in the work were fully anesthetized with ether.

Plastic Surgery of Blood-vessels and Direct Transfusion of Blood.—Dr. Isaac Levin read this paper. He said that plastic surgery of blood-vessels was one of the great achievements of modern experimental surgery. This late development of vascular surgery was due to the special difficulties encountered in dealing with this organ. In repairing a loss of continuity of such a tube, the surgeon, besides the usual aseptic precautious, had to take into consideration the possibility of a secondary hemorrhage and the formation of thrombosis with subsequent arrest of the circulation and embolism in some vital organ. Only in 1889 were reported the first successful results of the suturing of arterial wounds with preservation of the lumen of the vessels. Since then quite a number of investigators had studied the subject. Some had used different mechanical devices to unite the severed ends of the blood vessels; others produced the anastomosis with the help of sutures of various forms. Plastic surgery of blood vessels consisted in lateral sutures of veins and arteries, circular sutures of veins and arteries, arteriovenous anastomosis, and transplantation of arteries and veins. To implant an arterial segment successfully meant to avoid the formation of an intravascular thrombus after the operation. Blood remained fluid so long as it circulated in a vessel lined with an unimpaired living endothelium. Should the endothelium be injured through infection or trauma, a thrombus must form. In incomplete transplantations the segments certainly remained alive. In complete autoplastic and homoplastic transplantations, it seemed probable that the implanted segments remained alive. But in implantation of arterial segments of different animal species and segments, that had been kept for days in the refrigerator at a temperature between 0° and 1° C., the question presented itself whether these segments really remained alive, or whether it was possible to implant devitalized arterial segments; and the theories of intravascular coagulation of blood had to be revived. Dr. Levin had therefore performed in collaboration with Dr. John Larkin, a series of experiments with the transplantation of devitalized arterial segments. The technique followed in their operations was the one elaborated by Carrel. In the first series of experiments, they transplanted into the abdominal aorta of two dogs and two cats, segments of the abdominal aorta of the same species of animals placed for a few minutes in boiling water. In the second series they transplanted into the abdominal aorta of two dogs segments of a human ureter procured at a fresh autopsy and hardened in 4 per cent. formalin. In both series the circulation in the femoral arteries ceased very soon after the operation; there developed paralysis of the lower extremities, and the animals died within twenty-four hours after the operation. The autopsies showed that the implanted segment had collapsed and presented a much smaller lumen than the abdominal aorta of the host. In the third series of experiments they implanted in the abdominal aorta of two dogs and two cats, segments of the abdominal aorta of the same species hardened in 4 per cent. formalin. The segments selected had the same lumen as the aorta of the host. The result in every experiment was the formation of a thrombus, paralysis of the lower extremities, and death within two or three days after the operation. They then decided to select segments which would have at the time of operation a wider lumen than the aorta of the host. The operation was done on two dogs. The first did well for ten days; there was normal pulsation in both femoral arteries. On the eleventh day, the animal was found in the morning with protruding intestines. A secondary laparotomy was performed, but the dog died during the day. Both anastomoses held perfectly; the implanted piece was patent, without any thrombi The other animal did well for ten days. One the eleventh day they gave the animal anesthesia to dress the wound, and it died in a few hours, apparently from the influence of the ether. An analysis of these results showed that for ten days the circulating blood was passing through a dead canal and it remained fluid. It seemed, therefore, that blood need not necessarily run through a vessel lined with living endothelium in order to remain fluid. The implanted tube need have only a very smooth inner surface, its lumen corresponding perfectly to the lumen of the rest of the blood-vessel, and the line of anastomosis being perfectly smooth and even. While in plastic surgery the suture had proved to be of more value than the different cannulas, the temporary anastomosis required for the direct transfusion of blood was more readily and quickly accomplished with the aid of some mechanical appliance.

A Clamp Designed for Direct Blood Transfusion.—Dr. Isaac Levin presented this new instrument. This clamp required a less complicated technique and less time for the performance of the operation than Crile's instrument did. The instrument was an artery clamp without the grooves. At the tip of each blade there was attached a small cannula with a smooth bore. At the inner edge of each cannula there were attached four small pin points, and on the other surface of the cannula there were cut four grooves. When the clamp was closed, the pins of one cannula lay in the grooves of the other. The cannulas had a pyramidal form because the pins were bent outward. At the beginning of the operation both halves of the cannula were separated. The vein was pushed through one cannula and its wall was hooked on the pins. The same was done with the artery and the other half of the clamp. Then both halves of the clamp were united and clamped. When the clamp was closed, both blood-vessels were connected by the serous surfaces.

Dr. George E. Brewer said that he had had similar ideas to those expressed by Dr. Hartwell, and he believed that Dr. Crile's method with the cannula had an objection in being rather complicated and being difficult of performance. Dr. Brewer had experimented with this method and felt that he had developed a good technique; but when one was in a hurry, the circumstances surrounding the case were not so favorable. It had occurred to him that a simpler method was to be desired, and last spring he experimented further, with the result that it was his privilege to present two glass tubes that he had had made. At each end there was a small nodule and a sulcus in which the vessel was to be tied. It was coated within with liquid paraffin. These tubes he had tried on animals with perfect success. The operation was easy and results marvellous.

Dr. George Woolsey said that when he saw Dr. Crile do the operation a year and a half ago he thought it was an easy procedure; but in four cases that he had used the

Crile cannula, he had found the technique not so easy. But it should be borne in mind that after a few experiments the technique was not so difficult. The improvement was in the diminution of the time consumed in operating.

Dr. C. Clarence Sichel reported a case of transfusion performed on a woman who had a profuse hemorrhage following delivery, the donor being the husband. The glass tube was used and a perfect recovery followed the operation. The hemoglobin went from 19 per cent. to 25 per cent. and the red cells from 900,000 to 2,500,000 while the leucocytes diminished from 23,000 to 14,000.

Dr. Charles H. Peck said that he had used the cannula for transfusion in three cases and successfully.

Dr. Clarence A. McWilliams hoped that Dr. Hartwell's method would prove successful. He said he had had four cases in which he had transfused with the Crile cannula, two being successful, and two being failures. The failures were due to the fact that the radial arteries were small; the cannulas, too, were so small that when the vein was pulled through, there was no lumen left.

Dr. Charles A. Elsberg presented a simplified transfusion cannula which he had devised.

Case of Exarticulation of Shoulder for Carcinoma of the Humerus.—Dr. Joseph Wiener reported this case, which was illustrated by *x*-ray plates: The patient was a Russian, fifty-six years old. He had had endocarditis for several years. One and a half years ago he fell upon his elbow and said that he had a fracture at the upper third of the humerus. This was followed by good union. One year later (six months ago) he began to have pain in the right arm which steadily became worse. During the past two months there was almost complete disability of the right arm and forearm which he carried in a sling. He could pronate, supinate and flex the forearm only slightly. On examination the whole right upper extremity was seen to be atrophied from the disease. At the upper one-third of the humerus there was a bony tender swelling. The patient had chronic bronchitis, emphysema, endocarditis, etc. A small hard nodule was noted in the median lobe of the prostate. There were, however, no urinary symptoms. The fluoroscope showed bone in the upper one-third of the humerus almost completely destroyed. There was a thin shell of bone present and the entire medulla was occupied by a new growth. An exarticulation at the shoulder was performed. The tumor involved the shaft of the humerus and had perforated into the muscles. The diagnosis was made of metastatic carcinoma, possibly primary in the prostate.

Supracondyloid Fracture of the Left Humerus, with Malposition of Fragments.—Dr. Joseph Wiener reported the case of a boy, sixteen years old, who was admitted to the hospital September 14. Two and a half weeks before admission he ran into a fence while riding down hill on a bicycle, fracturing his arm above the left elbow. The arm was put up at the dispensary in full extension for a week. The arm was then put up in flexion with an anterior and posterior moulded splint and had remained in this position since the several *x*-ray pictures had been taken. Upon examination the arm was shown to be held at an angle of 110 and with great limitation of flexion and extension, only 10 flexion being possible. The outlines at the elbow were almost obliterated. The olecranon was not displaced. The distance from the oletranon to the internal condyle was normal. The distance from the olecranon to the external condyle was greatly increased. There was a large deposit of callus at the lower end of the humerus, chiefly around the external condyle. On September 16, a three-inch incision was made over the outer condyle and the line of fracture exposed. The upper fragment was found to be forward, the lower fragment was displaced backward and drawn upward by muscular action. The line of fracture was very oblique. Attempts to approximate the fragments by traction on the forearm and counterextension on the arm failed. Accordingly the lower end of the upper was freed of periosteum and a section of the bone was sawn off obliquely on the posterior aspect of the upper fragment in such a manner that it could be properly and perfectly approximated to the upper surface of the lower fragment. The two fragments were then approximated by a few chromic sutures, as well as the periosteum. A single nail was then hammered through both fragments. The muscles were sutured. The elbow was not opened. The arm was placed in plaster-of-paris at an angle of 110°. Twenty-one days later the wound was found to have healed by primary union. The stitches were removed and the nail easily withdrawn. The arm was placed in a sling. On October 23 the adhesions were broken up under gas. The patient left the hospital with almost complete extension and flexion to 110°.

Pathological Society of Philadelphia.

At a stated meeting held February 12 Drs. Arthur V. Meigs and C. B. Farr exhibited "A Heart Showing an Extreme Degree of Aortic and Mitral Stenosis." The specimen came from a woman 66 years old and the lesions were known to have existed for 57 years, though three generations of physicians in one family. Dr. John Funke exhibited a specimen of "Lymphosarcoma Involving the Omentum." The omentum was the seat of an enormous number of growths of varying size, while the pelvis contained quite a large tumor. Dr. Funke exhibited also "A Heart With a Congenital Malformation." The foramen of Botal was but partially closed, the orifice of the pulmonary artery was greatly diminished in size, the ductus arteriosus was patulous, while the aorta had a joint origin from both ventricles. Dr. Funke further exhibited for Dr. W. M. L. Coplin preparations of gelatin demonstrative of the mechanism of the development of edema. The application of formic acid gave rise to the formation of an elevation on the surface of the gelatin, and this could be prevented by the previous application of other substances of different reaction, such as fuchsin. The phenomenon was intended to illustrate the physiochemical origin of edema. Dr. R. S. Lavenson exhibited a specimen of "Sacculated Aneurysm of Arch of the Aorta and Cylindrical Aneurysm of the Descending Aorta." Dr. H. S. Wieder exhibited a specimen of "Ruptured Double Sacculated Aneurysm of the Arch of the Aorta." The specimen came from a woman who had had right hemiplegia and aphasia and who died suddenly without obvious cause. The first aneurysm arose from the arch of the aorta, while the second involved also the innominate and the left carotid and subclavian arteries. In celebration of the hundredth anniversary of the birth of Charles Darwin, Dr. Arthur Erwin Brown delivered an address entitled "Darwin and His Work." He pointed out that the Philadelphia Academy of the Natural Sciences was one of the first learned body to confer honorary membership on Darwin following the publication of his "Origin of Species," and he dwelt upon the several phases of Darwin's life, how he failed to exhibit any fondness for medicine or the ministry, and how his opportunity came in the fitting out of the brig-of-war "Beagle" for a voyage of scientific exploration, Darwin receiving appointment as naturalist to the expedition. The expedition occupied five years, during most of which, while at sea, Darwin was sick. However, he made a vast number of observations, which furnished the basis for forty years of subsequent literary and scientific activity, in the face of serious physical disability resulting from impairment of health consequent upon his earlier voyage. Dr. Chas. W. Burr delivered an address on "The Influence of Darwin on Medical Thought."

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

North Dakota State Board of Medical Examiners.

Grand Forks, October 6, 1908.

ANATOMY.

1. Name the coverings of an oblique inguinal hernia.
2. Bound the axilla and name the contents of the axillary space.
3. Describe the femur and the joints which it forms a part of.
4. Where is Poupart's ligament? What structures lie beneath it?
5. Locate and describe the gall-bladder and ducts.
6. Describe the colon and give its relation to other abdominal organs.
7. Name the divisions of the auditory apparatus.

HISTOLOGY.

1. Describe fully the process of indirect cell-division.
2. Name and describe fully the cells found in the red marrow.
3. Describe a non-medullated nerve fibre and tell where they occur.
4. Give the histology of the stomach and describe the differences between the pyloric and cardiac ends.
5. Give the histology of the nasal mucous membrane.

PHYSIOLOGY.

1. Describe the course of the blood through the heart. Give the causes of the heart sounds.
2. What factors produce pulsation in the arteries?
3. Describe and give an example of reflex movement.
4. Give the composition of pancreatic juice. Mention the foods it acts upon.
5. What changes take place in the blood during its passage through the lungs?
6. Describe the process of coagulation of blood.

CHEMISTRY AND TEXICOLOGY.

1. Define organic chemistry.
2. Describe Heller's test and discuss its value.
3. Define (*a*) specific gravity, (*b*) an acid.
4. Describe the indican test in urine. Of what value is it?
5. How would you decide whether a patient was suffering from opium poisoning or uremic coma?
6. Describe condition of a patient ten minutes after drinking one ounce of carbolic acid. What treatment would you order?
7. Give symptoms and treatment of opium poisoning.
8. Give antidotes for poisoning by (*a*) aconite, (*b*) corrosive sublimate, (*c*) "poison fly paper."

MATERIA MEDICA.

1. What is an escharotic? Give names of three.
2. Write prescription for a suppository for irritable hemorrhoids.
3. Give dose of following: (1) urotropine, (2) phenacetine, (3) extract of opium, (4) sulphate of atropine, (5) trional, (6) sulphate of strychnine, (7) sodium salicylate, (8) tincture of strophanthus, (9) Dover's powder, (10) aromatic spirit of ammonia.
4. Define the following: (1) analgesic, (2) narcotic, (3) hypnotic, (4) sudorific, (5) mydriatic, (6) hepatic stimulant, (7) anthelmintic, (8) collyrium, (9) ecbolic.
5. Name all the different methods of administering drugs.
6. What official glandular extracts do we have, and from what obtained?
7. Give antidotes for following: (1) arsenic, (2) strychnine, (3) iodine, (4) phenol, (5) cocaine sulphate.
8. Name the official preparations of opium and the dose of each.
9. From what is pilocarpine hydrochlorate derived? Give its dose and physiological action.
10. Name contraindications for the use of digitalis.

PATHOLOGY.

(Answer any five questions.)

1. Give the pathology of acute tonsillitis.
2. What are some of the cardinal signs of inflammation?
3. Describe the changes occurring in the lymphatic structures in typhoid fever.
4. What is gonorrhea?
5. Give the pathology of acute dysentery.
6. What are cysts? How are cysts formed? Give the varieties of cysts.
7. Give the pathology of the false membrane of the throat in diphtheria.
8. Mention the neoplasms. Describe a slough.

PRACTICE.

1. What is angina pectoris and with what may it be confounded?
2. Define hemoptysis, etiology, prognosis, treatment.
3. What is edema of the lungs, and what medicines will produce it?
4. What is asthma, and why do the paroxysms usually occur at night?
5. What is myxedema, and what treatment gives best results?
6. Scorbutus—predisposing causes, symptoms, diagnosis, prognosis, treatment?
7. How would you handle a case of diabetes insipidus?
8. What is muscular rheumatism? Name some varieties.
9. Given a case of incipient tuberculosis—your method of taking care of it, based on latest scientific principles.
10. Define and treat a case of erysipelas.

SURGERY.

1. What are the indications for trephining the skull, and describe your method?
2. How would you treat a simple fracture of the femur at the middle third?
3. Give diagnosis and treatment of osteomyelitis.
4. How would you administer ether? How guard against accidents, and what are the contraindications for its use?
5. How would you treat a fracture of the inferior maxillary bone?

DISEASES OF WOMEN AND CHILDREN.

1. Give treatment, local and general, for leucorrhea.
2. What is salpingitis? Give etiology and treatment.
3. Differentiate ovaritis from appendicitis.
4. Give the symptoms, diagnosis, and treatment of vomiting in pregnancy.
5. Cause and treatment of dysmenorrhea.
6. Write a prescription for treatment of acute eczema, in infant.
7. Diagnosis and treatment of whooping cough.
8. Differential diagnosis between scarlet fever, measles, and German measles.

OBSTETRICS.

1. Name subjective and objective signs of pregnancy.
2. Causes and treatment of post-partum hemorrhage.
3. Etiology, symptoms, and treatment of placenta prævia.
4. Your treatment of abortion.
5. Describe your first case of labor.

NERVOUS DISEASES.

1. Define Cheyne-Stokes respiration; give its diagnostic significance.
2. What is the significance of the patellar reflex as a sign of disease?
3. Give causes, symptoms, and prognosis of Bell's paralysis.
4. Describe the symptoms and treatment of a case of apoplexy due to cerebral hemorrhage.
5. Give symptoms and treatment of locomotor ataxia.

EYE AND EAR.

1. How would you treat conjunctivitis of gonorrheal origin?
2. What are the causes of iritis? Give your treatment.
3. Give causes and treatment of mastoiditis.
4. How would you perform paracentesis of the membrana tympani?
5. Give causes and treatment of earache.

MEDICAL JURISPRUDENCE.

1. (*a*) After receiving a license to practise medicine, surgery, and obstetrics in the State of North Dakota, what must the recipient do with the same before he can legally embark upon the practice of his profession?

(*b*) What is the penalty for practicing medicine, surgery, or obstetrics in this State without complying with the law?

(*c*) Is a duly licensed physician exempt from jury duty in the courts of justice in this State?

(*d*) When a physician has knowledge of a contagious, epidemic, or infectious disease within the jurisdiction of a local board of health, what does the law of this State require him to do?

(*e*) In case of the death of a patient, what does the law of this State require of all practicing physicians concerning the report of the same?

2. (*a*) Give six commonly known signs of death.

(*b*) Is it possible to determine to an absolute certainty without postmortem, whether or not death has in fact occurred? If so, how?

3. Give the usual motives which, in a general way underlie malingering, and state what general observations would assist you in differentiating between the feigned and the real condition of a suspect.

4. (*a*) What is medical expert testimony?

(*b*) Upon what is it based?

(*c*) Who is qualified to give it?

(*d*) Distinguish between medical expert testimony and positive testimony.

5. (*a*) Define malpractice.

(*b*) What is the statutory limitation for the commencement of a civil action against a physician in this State, to recover damages for alleged malpractice?

(*c*) Is a physician by law authorized to perform an abortion under any circumstances?

(*d*) Is a successful abortion, performed with criminal intent, but with great skill and for compensation, in a case where the parties interested desire such an operation, in law malpractice.

PREVENTIVE MEDICINE.

1. How would you fumigate for smallpox, in the country?

2. If called to a family with diphtheria, what would be your course regarding: (*a*) Those afflicted with the disease, (*b*) those who have not, (*c*) the community at large.

3. Name all the diseases that you know might result from drinking impure water, and how prevent them.

4. Outline a plan for the disposal of garbage and sewage in a prairie town of 1,500 people.

5. How is glanders contracted in man, and how prevented?

6. Name two important diseases that may be contracted from milk and what steps could be taken toward preventing same?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

NORTH DAKOTA STATE BOARD OF MEDICAL EXAMINERS.

Grand Forks, October 6, 1908.

ANATOMY.

1. *The coverings of an oblique inguinal hernia* are from without inwards: Skin, Superficial fascia, Intercolumnar fascia, Cremasteric fascia, Infundibuliform fascia, Subperitoneal areolar tissue, and Peritoneum.

2. The axilla is *bounded: Anteriorly*, by the clavicle, Subclavius, Pectoralis major, costocoracoid membrane, Pectoralis minor; *posteriorly*, by the Subscapularis, Teres major, and Latissimus dorsi; *internally*, by the first four ribs, first three Intercostal muscles, Serratus magnus; *externally*, by the humerus, Coracobrachialis, and Biceps.

Contents: Axillary vessels; brachial plexus of nerves and their branches; some branches of the intercostal nerves; lymphatic glands, fat, and loose areolar tissue.

4. *Poupart's ligament* is the lower border of the aponeurosis of the External oblique, and extends from the anterior superior spine of the ilium to the spine of the pubis.

The anatomical structures which lie beneath Poupart's ligament are (from without inward): External cutaneous nerve, Iliacus, anterior crural nerve, Psoas, femoral artery, femoral vein, femoral ring.

6. The COLON is divided into ascending, transverse, descending, iliac, and pelvic.

The *ascending colon* extends from the cecum to the under surface of the liver to the right of the gall bladder, where it turns to the left, forming the *hepatic flexure*. It lies in the right iliac and right hypochrondriac regions. The peritoneum covers the anterior and lateral surfaces. Length, 8 inches.

Relations.—In front: The convolutions of the ileum

Behind: Iliacus, quadratus lumborum, outer side of right kidney.

The *transverse colon* passes from right to left, from the gall-bladder to the spleen. It forms an arch, convex anteriorly and below: *the transverse arch of the colon*. It is entirely surrounded by peritoneum, which is attached posteriorly to the spine, forming the meso-colon. Length, 20 inches.

Relations.—Above: Liver, gall-bladder, large curvature of stomach, lower end of spleen.

Below: Small intestines.

Anteriorly: Anterior layers of great omentum, anterior abdominal wall.

Posteriorly: Right kidney, second part of duodenum, transverse meso-colon, panereas, and small intestines.

The *descending colon* passes from the end of the transverse colon by a bend, *the splenic flexure*. Between the splenic flexure and the diaphragm, opposite the tenth left rib, is a fold of the peritoneum, the *costocolic ligament*, which slings up the spleen. The gut then passes downwards to the iliac crest, ending in the iliac colon. The peritoneum invests its anterior and lateral surfaces. Length, 4 to 6 inches.

Relations.—Behind: Left crus, left kidney, quadratus lumborum, and psoas.

In front: Small intestines.

Inner side: Outer border of left kidney.

The *iliac colon* is continuous with the descending colon at the left iliac crest, and ends at the inner border of the left psoas. Peritoneum invests its anterior and lateral surfaces; it has no mesentery. Length, 5 to 6 inches.

Relations.—In front: Small intestines; when distended, the anterior abdominal wall.

Behind: Left ilio-psoas.

The *pelvic colon* extends from the inner border of the psoas to the level of the third sacral vertebra. Length, 16 or 17 inches; very variable. It has an extensive mesentery.

Relations.—Passing over left brim of pelvis, it crosses the left external iliac vessels and left ureter, and passes to right margin of pelvis, resting on bladder in male and uterus in female; above lie coils of small intestine. It then turns back to mid-line on posterior wall of pelvis, and forming a second bend, descends to end in the rectum. (From *Aids to Anatomy.*)

7. The *auditory apparatus* is divided into: (1) The external ear; (2) the middle ear, or tympanum; and (3) the internal ear, or labyrinth.

PHYSIOLOGY.

1. The *causes* producing the *first* sound of the heart are not definitely ascertained; the following are supposed to be causatory factors: (1) The vibration and closure of the auriculo-ventricular valves, (2) the muscular sound produced by the contraction of the ventricles, and (3) the cardiac impulse against the chest wall.

The *second* sound is caused by the vibration due to the closure of the semilunar valves.

2. *Pulsation in the arteries is caused by:* The ventricular systole, the elasticity of the arterial walls, and the volume of blood in the vessels.

3. *Reflex movements* are involuntary or unconscious movements, due to suitable stimuli. They depend upon the integrity of the *reflex arc*, which is a complex made up of: (1) A surface capable of receiving an impression; (2) an afferent nerve; (3) a nerve cell capable of receiving and also of sending out impulses; (4) an efferent nerve, and (5) a surface capable of responding in some way to the impulse conveyed by the efferent nerve.

Reflexes are classified as: (1) Superficial, (2) deep, and (3) visceral.

Example: The patellar reflex consists of a contraction of the extensor muscles of the leg and a movement of the foot forward when the ligamentum patellæ is struck: the quadriceps extensor must first be slightly stretched by putting one knee over the other. Its integrity depends upon a healthy condition of the entire reflex arc, consisting of tendon, afferent or sensory nerve, posterior roots, and anterior horn of the spinal cord, the efferent or motor nerve, and the muscle itself.

4. *Composition of pancreatic juice:* Water and solids, the latter consisting of three enzymes (trypsin, amylopsin, and steapsin), proteid material, soaps, fats, lecithin, and inorganic salts (carbonate of sodium, chloride of sodium, and phosphates of sodium, calcium, and magnesium).

It acts upon proteids, fats, and starches.

5. The changes which take place in the blood during its passage through the lungs, are: (1) the giving up of CO_2 by the venous blood, (2) the absorption of oxygen during inspiration, (3) the blood is cooled, and (4) it also loses a small amount of watery vapor

6. When blood is withdrawn from the blood vessels of the living body, it first becomes viscid, then sets, and is

converted into a jelly-like mass. This is due to the formation of fibrin. The jelly contracts, forming the clot; and at the same time the serum is squeezed out from the clot. Various circumstances and conditions will hasten or delay the process of coagulation. In man, the blood generally becomes viscid in from two to three minutes; it forms the jelly-like mass in from five to six minutes; a few minutes later the serum begins to appear; and the whole process is completed in from twenty-four to thirty-six hours. The clot then floats in the serum. The process is thus summed up by Haliburton: In the plasma a proteid substance exists, called Fibrinogen. From the colorless corpuscles a nucleo-proteid is shed out, called Prothrombin. By the action of calcium salts prothrombin is converted into fibrin ferment, or Thrombin. Thrombin acts on fibrinogen in such a way that two new substances are formed: one of these is unimportant and remains in solution; the other is important, viz., Fibrin, which entangles the corpuscles, and so forms the clot.

CHEMISTRY AND TOXICOLOGY.

1. *Organic chemistry* is the chemistry of the carbon compounds.

2. *Heller's test for albumin in the urine:* "Place in a test-tube a layer of HNO_3 about 2 centim, in thickness; then, with a pipette, carefully float upon the surface of this a layer of the urine in such a manner that the liquids do not mix. If albumin be present, a cloudy ring appears *at* the point of junction of the two layers, the borders of the cloud being sharply defined. A cloudy ring may be formed by the presence of an excess of urates, but in this case it is not *at,* but *above,* the point of junction of the layers, and its upper border is not sharply defined, but fades off gradually." (Witthaus' *Essentials of Chemistry.*)

3. (*a*) *Specific gravity* of a substance is the weight of a given volume of that substance as compared with the weight of an equal volume of some other substance taken as a standard of comparison, under like conditions of temperature and pressure.

(b) An *acid* is a compound of an electro-negative element or radical with hydrogen, part or all of which hydrogen it can part with in exchange for an electro-positive element without the formation of a base.

4. *Test for indican in the urine:* The urine is mixed with one-fifth its volume of 20 per cent. solution of lead acetate and filtered. The filtrate is mixed with an equal volume of fuming hydrochloric acid containing 3:1000 of ferric chloride, a few drops of chloroform are added, and the mixture strongly shaken one to two minutes. With normal urine the chloroform remains colorless, or almost so; but if an excess of indoxyl compounds be present the chloroform is colored blue, and the depth of the color is a rough indication of the degree of the excess.—(From Witthaus' *Essentials of Chemistry.*)

Excess of indican is found in the urine "in hypochlorhydria; in hyperchlorhydria of gastric ulcer; in conditions in which there is diminished peristalsis of the small intestines, as in ileus and peritonitis, not in simple constipation; also in conditions in which putrefactive changes occur in the body elsewhere than in the intestine, as in empyema, putrid bronchitis, gangrene of the lungs, etc."

5. In *uræmic coma* there may be a urinous odor to the breath, the urine is scanty and contains albumin, there is slow pulse with high arterial tension, the pupils are usually small and equal, respiration is deep and may be quickened, the body temperature may be above normal or subnormal.

In *opium coma* the pupils are contracted, respiration is slow, pulse slow and full, body temperature is normal or subnormal, there may be the odor of laudanum on the breath. There may be death, or complete collapse.

6. *Symptoms of carbolic acid poisoning:* Buccal mucous membrane is whitened and hardened; vomiting; burning pain in mouth, esophagus, and stomach; pulse and body temperature are lowered; the pupils are contracted; collapse, and finally death. The urine may become dark.

Treatment: Emetics, white of egg, stimulants. Alcohol is said to be antidotal.

7. *Opium poisoning: Symptoms:*—In opium poisoning there may be three stages: (1) a period of excitement, in which the patient is active, talkative, and has hallucinations; (2) a period of drowsiness, in which the patient is sleepy, but may be aroused; his face is pale, lips livid, pupils contracted; this passes into (3) the stage of coma, from which the patient cannot be aroused, the reflexes are abolished, the pupils are very contracted, the pulse is slow and irregular, and the respirations are infrequent and shallow.

Treatment consists in washing out the stomach, preferably with a dilute solution of potassium permanganate; ambulatory treatment, to keep the patient awake; artificial respiration is indicated, and strong coffee should be administered by the mouth or rectum; the bladder should be emptied by the catheter.

8. The *antidotes* for poisoning: by (*a*) *aconite,* are digitalis, strychnin, atropin, and amyl nitrite; (*b*) *corrosive sublimate,* white of egg in moderate quantity, followed by an emetic; (*c*) *"poison fly paper,"* the antidote is that for arsenic, *viz.,* freshly prepared ferric hydroxide.

MATERIA MEDICA.

1. *Escharotics* are agents which destroy tissues to which they are applied, and produce a slough.

Three escharotics: Cautery, nitric acid, silver nitrate.

2. Prescription for a suppository for irritable hemorrhoids:

℞. Extracti opii, gr. x.
Extracti belladonnæ, gr. iij.
Olei theobromatis, 3ijss. Misce.
Fiant suppositoria No. x.

Sig: Introduce one into the rectum at bed time.

3. *Dose:* of (1) urotropin, gr. iv; (2) phenacetine, gr. vijss; (3) extract of opium, gr. ss; (4) sulphate of atropine, gr. 1/160; (5) trional, gr. xv; (6) sulphate of strychnine, gr. 1/64; (7) sodium salicylate, gr. xv; (8) tincture of strophanthus, ℥viij; (9) Dover's powder, gr. vijss; (10) aromatic spirit of ammonia, ℥xxx.

4. (1) *Analgesic* is an agent which relieves pain, by blunting sensation.

(2) *Narcotic* is an agent which produces profound sleep, and may depress the respiratory and circulatory functions.

(3) *Hypnotic* is an agent which produces sleep somewhat resembling natural sleep.

(4) *Sudorific* is an agent which promotes the secretion of sweat.

(5) *Mydriatic* is an agent which dilates the pupil.

(6) *Hepatic stimulant* is an agent which increases the activity of the liver cells, and the secretion of bile.

(7) *Anthelmintic* is an agent which destroys or removes intestinal worms.

(8) *Collyrium* is an eyewash.

(9) *Ecbolic* is an agent which tends to make the uterus contract; it may, therefore, produce an abortion.

5. *The different methods of administering drugs,* are: By the mouth, stomach, rectum, inhalation, inunction, hypodermatically, by inoculation, cataphoresis.

6. The *official glandular extracts* are: Pepsine (from the stomach of the hog); Pancreatin (from the enzymes in the pancreas of the hog); Desiccated thyroid glands (from the thyroid of the sheep); Desiccated Suprarenal glands (from the suprarenals of the sheep).

7. The *antidote:* (1) for *arsenic,* is freshly prepared ferric hydroxide; (2) for *strychnine,* is chloroform, chloral, tannic acid; (3) for *iodine,* is starch; (4) for *phenol,* is alcohol, or sodium sulphate, (5) for *cocaine hydrochloride,* chloral, chloroform, strychnine.

8. *The official preparations of opium, with doses:* Powdered opium, gr. j; extract of opium, gr. ss; powder of ipecac and opium, gr. vijss; vinegar of opium, ℥viij; tincture of opium, ℥viij; camphorated tincture of opium, 3ij; deodorated tincture of opium, ℥viij; granulated opium, gr. jss; wine of opium, ℥viij; morphine, gr. 1/5; morphine sulphate, acetate, and hydrochloride, each, gr. 1/4; codeine, gr. 1/2; codeine sulphate and phosphate, each, gr. 1/2; apomorphine hydrochloride, gr. 1/10.

9. Pilocarpine hydrochloride is derived from Pilocarpus Jaborandi. The dose is gr. 1/5. It causes increase of saliva and of perspiration; increased peristalsis; it increases and then diminishes blood pressure and heart action; it causes the pupil to contract; and depresses the nervous system.

10. Digitalis is contraindicated in diseases of the heart (1) in aortic lesions when uncombined with mitral lesions; (2) when the heart action is strong and arterial tension high.

PATHOLOGY.

1. In *acute tonsillitis,* the mucous membrane covering the tonsil is inflamed, the crypts are also similarly affected and become filled with exudate which, later, appears as cheesy material composed of epithelium and micrococci. The tonsils are enlarged and hyperæmic. The exudation covers the tonsils and looks like the false membrane of diphtheria.

2. The cardinal signs of inflammation, are: Redness, swelling, pain, heat, and disordered function.

3. The lymphatic structures involved in typhoid fever, are the lymphatics of the intestines, mesenteric glands and spleen. In the first stage of typhoid fever Peyer's patches

become swollen, hyperemic, and reddened; a few days later they appear as whitish or gray elevations, and the hyperemia has disappeared; the surface of the patch is smooth and its edge is sharply defined; after the first week necrosis may occur; the center of the patch becomes softer, more yellow, or sometimes even red from the absorption of blood pigment. The necrotic portion falls off, leaving an irregular ulcer with necrotic and undermined edges. These ulcers are elongated, with the long axis parallel with that of the intestine, and a smooth floor. The ulcers may heal or go on to perforation.

The spleen becomes congested and enlarged, is liable to infarction, and contains the bacilli.

4. *Gonorrhea* is a specific contagious disease; usually affecting the urethral mucous membrane in males, and the vulva in females. It is generally acquired from sexual intercourse, and is due to the Gonococcus of Neisser.

5. In amebic dysentery the mucosa of the large intestine is edematous and infiltrated, and finally ulcerated. These ulcers have undermined edges, and several of them may coalesce or connect by means of sinuses; the mouth of the ulcer is comparatively small. Much of the mucosa may be necrosed and slough, and the ulceration may extend down to the muscular coat or even to the serous coat of the intestine. Occasionally the lower portion of the ileum is involved as well as the large intestine. Perforation is rare.

The condition is due to the *Ameba dysenteriæ* or *Ameba coli*, an ameboid body, three or four times as large as a red blood corpuscle, granular in the center and clear at the margin, nucleated, and containing vacuoles, sometimes also containing pigment, bacteria, or other foreign matter.

Abscess of the liver is often associated with this condition.

6. A *cyst* is a circumscribed cavity containing liquid or pultaceous material. Cysts may be *formed:* (1) By the accumulation of secretions and other products within cavities which are already in existence; and (2) independently, by the softening or liquefaction of tissues.

Varieties: Retention cysts, dilatation cysts, exudation cysts, extravasation cysts, parasitic cysts, congenital cysts, dermoid cysts.

7. The false membrane consists of fibrin, degenerated leucocytes and epithelial cells, and a few red cells. It is tough, elastic, covers and is adherent to the mucous membrane; but it does not penetrate the submucosa. The mucosa degenerates and becomes necrosed. In the membrane are also found the Klebs-Loeffler bacillus and other bacteria (chiefly cocci).

8. The *neoplasms* are: Myoma, neuroma, angioma, lymphangioma, lymphadenoma, fibroma, myxoma, lipoma, chondroma, osteoma, sarcoma, glioma, adenoma, papilloma, epithelioma, carcinoma.

A *slough* is a disorganized portion arising from the mortification of a part, and distinguishable from the living parts by its color, consistence, and other physical properties. Inflammation excited in the contiguous parts gives occasion to a secretion of pus between the living and dead parts, ultimately completely separating the latter.

PRACTICE.

1. *Angina pectoris* is a paroxysmal affection, characterized by agonizing pain over the region of the heart, faintness, and anxiety; of more or less sudden onset, and associated with a dread of impending death.

It may be confounded with pseudo-angina, locomotor ataxia, and gastralgia.

2. Hemoptysis is a condition in which an appreciable amount of blood is spit up.

Etiology: Pulmonary tuberculosis, lobar pneumonia, bronchiectasis, abscess or gangrene of the lung, valvular disease of the heart causing pulmonary venous obstruction, cardiac hypertrophy, rupture of thoracic or innominate aneurysm, hemophilia, scurvy, purpura, vicarious menstruation.

Prognosis: depends upon the cause; it may be good or extremely grave.

3. *Edema of the lungs* is a condition in which, owing to extreme congestion of the lungs, serum is transuded from the distended capillaries into the alveoli and their walls.

Medicine that will produce it: Pilocarpine.

4. *Asthma* is a condition in which there are paroxysmal attacks of dyspnea, due to spasm of the bronchi, or to sudden swelling of the bronchial mucous membrane.

5. *Myxedema* is a condition characterized by atrophy of the thyroid gland, mental dullness, sluggish movements, and thick speech.

The best results are probably obtained from the administration of thyroid extract.

8. *Muscular rheumatism* is a condition characterized by pain, spasm, and rigidity in certain of the voluntary muscles.

The *varieties*, are: Lumbago, Torticollis, Pleurodynia, and Cephalodynia.

DISEASES OF WOMEN AND CHILDREN.

3. In *ovaritis* the pain is not localized, but may be bilateral, and spreads to the vagina and rectum; there is no tenderness at McBurney's point; it is usually worse just before the menstrual period, which sometimes affords relief; on vaginal examination the ovary is found to be tender.

In *appendicitis* the pain is of sudden onset, and is localized in the right iliac fossa; there is abdominal rigidity, chiefly of the right rectus muscle, and tenderness at McBurney's point; there are usually fever, nausea, vomiting, and constipation.

6. For *acute eczema in an infant*, Holt recommends:

℞. Pulveris calaminæ præparatæ..... ʒij
Zinci oxidi ..... ʒss
Glycerini ..... ʒj
Liquoris calcis ..... ʒij
Aquæ rosæ ..... ʒviij Misce.

A piece of muslin should be dipped in this solution, and applied to the affected part, being kept in place by a bandage. If there is much itching 1 per cent. of carbolic acid may be added.

8. *Scarlet fever.* Period of incubation, from a few hours to seven days. Stage of invasion, twenty-four hours. Character of eruption, a scarlet punctate rash, beginning on neck and chest, then covering face and body; desquamation is scaly or in flakes. The eruption is brighter, is on a red background, punctiform, and is more uniform; the temperature is higher, the pulse quicker; the tongue is of the "strawberry" type, the lymphatics in the neck may be swollen, and there is sore throat; Koplik's spots are absent.

Measles. Period of incubation, ten to twelve days. Stage of invasion, four days. Character of eruption, small dark red papules with crescentic borders, beginning on face and rapidly spreading over the entire body; desquamation is branny. The eruption is darker, less uniform, more shotty; the temperature is lower, pulse slower, the tongue is not of the "strawberry" type; coryza, coughing, and sneezing may be present; Koplik's spots are present.

German Measles. Period of incubation, ten to seventeen days. Stage of invasion one day. Eruption appears on first day, is most intense on second day, consists of red papules, often fades from face before it is seen on the limbs. The pulse is not much accelerated, all the symptoms are slight. Desquamation is very slight. There may be slight sore throat and swollen cervical glands. Koplik's spots are absent.

OBSTETRICS.

1. The *subjective* signs of pregnancy are: Cessation of menstruation, morning sickness, increased frequency of urination, active fetal movements.

The *objective* signs of pregnancy are: Softening of the cervix, changes in the mammary glands, discoloration of the vulva and vagina, pulsation in the vaginal vault, Hegar's sign, active fetal movements, ballottement, palpation of the fetus, intermittent uterine contractions, hearing the fetal heart-beat, rate of growth of the uterine tumor.

NERVOUS DISEASES.

1. In *Cheyne-Stokes respiration* the respirations gradually increase in volume and rapidity until they reach a climax, when they gradually subside, and finally cease for from ten to forty seconds, when the same cycle begins again.

It generally denotes a fatal issue.

It is found in apoplexy, brain tumor, meningitis, fatty degeneration of the heart, uræmia, diabetes, and some infectious diseases.

2. The *patellar reflex* is nearly always present in health, and denotes a healthy condition of the entire reflex arc (tendon, afferent, or sensory nerve, posterior roots and anterior horn of the spinal cord, the efferent or motor nerve, and the muscle itself). It is *absent* when there is a lesion which affects any part of this reflex arc; such is the case in locomotor ataxia, poliomyelitis, Landry's paralysis, neuritis, in apoplexy just after the shock, and in epilepsy following the convulsion, etc. It is *exaggerated* in irritability of the spinal cord, organic diseases of the cerebrum, and some incomplete lesions of the cord.

MEDICAL JURISPRUDENCE.

1. (*a*) After receiving a license to practise medicine, surgery, and obstetrics in the State of North Dakota, the

recipient must file it for record, with the register of deeds of the county wherein he resides, before he can legally embark upon the practice of his profession.

(*b*) The penalty for practising medicine, surgery, or obstetrics, in North Dakota, without complying with the law, is: A fine of from $50 to $100, or imprisonment in a county jail not exceeding thirty days, or both.

2. (*a*) *Six commonly known signs of death:* (1) Complete and permanent cessation of circulation; (2) complete and permanent cessation of respiration; (3) rigor mortis; (4) loss of bodily heat; (5) pallor of the body; (6) putrefaction.

(*b*) Yes; putrefaction is generally allowed to be an absolutely certain sign of death.

4. In *expert* testimony, the witness may give his *opinion* on facts or supposed facts as noted by himself or asserted by others. *Theoretically,* this can be done only by those perfectly familiar with the subject in question; but *practically* any (or almost any) physician with a license to practise is accepted as an expert witness.

In *ordinary* testimony, the witness testifies only to *facts* which he has seen, or heard, or with which he has become acquainted by personal observation.

5. (*a*) Malpractice is a failure on the part of a medical practitioner to use such skill, care, and judgment in the treatment of a patient as the law requires; and thereby the patient suffers damage. If due to negligence only, it is *civil* malpractice. But if done deliberately, or wrongfully, or if gross carelessness or neglect have been shown, or if some illegal operation (such as criminal abortion) be performed, it is *criminal malpractice.*

(*c*) If an abortion is absolutely necessary, a physician is authorized by law to perform it, to the same extent as he is authorized by law to perform any other surgical procedure.

(*d*) Yes; if performed *with criminal intent,* it is malpractice.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION		
Alabama*	W. H. Sanders, Montgomery	Montgomery	July	13
Arizona*	Ancil Martin, Phoenix	Phoenix	April	5
Arkansas*	F. T. Murphy, Brinkley	Little Rock	April	13
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco	April	6
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	April	6
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	July	13
Delaware	J. H. Wilson, Dover	Dover	June	15
Dist. of Col'bia	Geo. C. Ober, Washington	Washington	April	13
Florida*	J. D. Fernandez, Jacksonville	Tallahassee	May	19
Georgia	E. E. Anthony, Griffin	Atlanta, Augusta	May	—
Idaho	W. F. Howard, Pocatello	Boise	April	6
Illinois	J. A. Egan, Springfield	Chicago	April	15
Indiana	W. T. Gott, Indianapolis	Indianapolis	May	25
Iowa	Louis A. Thomas, Des Moines	Des Moines		
Kansas	D. P. Cook, Clay Center	Kansas City	June	8
Kentucky*	J. N. McCormick, Bowling Green	Louisville	April	27
Louisiana	F. A. LaRue, 211 Camp Street, New Orleans	New Orleans	May	20
Maine	Wm. J. Maybury, Saco	Portland		
Maryland	J. McP. Scott, Hagerstown	Baltimore	June	15
Massachusetts*	E. B. Harvey, State House, Boston	Boston	May	11
Michigan	B. D. Hanson, 205 Whitney Building, Detroit	Ann Arbor	June	8
Minnesota	W. S. Fullerton, St. Paul	St. Paul	April	6
Mississippi	S. H. McLean, Jackson	Jackson	May	11
Missouri	J. A. B. Adcock, Warrensburg	Kansas City	May	4
Montana*	Wm. C. Riddell, Helena	Helena	April	6
Nebraska	E. J. C. Sward, Oakland	Lincoln		
Nevada	S. L. Lee, Carson City	Carson City	May	3
N. Hampshire*	Henry C. Morrison, State Library, Concord	Concord	July	—
New Jersey	J. W. Bennett, Long Branch	Trenton	June	15
New Mexico	J. A. Massie, Santa Fe	Santa Fe	April	12
New York	C. P. Wheelock, Univ. of State of New York, Albany	New York, Albany, Syracuse, Buffalo	Feb.	2
N. Carolina*	B. K. Hays, Oxford	Asheville	June	9
N. Dakota	H. M. Wheeler, Grand Forks	Grand Forks	April	6
Ohio	Geo. H. Matson, Columbus	Columbus	June	8
Oklahoma*	F. P. Davis, Enid	Chicasha		
Oregon	B. E. Miller, Portland	Portland	July	6
Pennsylvania	N. C. Schaeffer, Harrisburg	Philadelphia, Pittsburg	June	22
Rhode Island	G. T. Swarts, Providence	Providence	April	1
S. Carolina	H. H. Wyman, Aiken	Columbia	June	8
S. Dakota	H. E. McNutt, Aberdeen	Watertown	July	14
Tennessee*	T. J. Happel, Trenton	Memphis, Nashville, Knoxville	May	—
Texas	M. E. Daniel, Honey Grove	Cleburne	June	22
Utah*	R. W. Fisher, Salt Lake City	Salt Lake City	April	5
Vermont	W. Scott Nay, Underhill	Burlington	July	13
Virginia	R. S. Martin, Stuart	Richmond	June	22
Washington*	K. Turner, Seattle	Seattle	July	6
W. Virginia	H. A. Barbee, Point Pleasant	Huntington	April	13
Wisconsin	J. V. Stevens, Jefferson	Madison	July	13
Wyoming	S. B. Miller, Laramie	Laramie	June	23

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for latest details regarding the examination in any particular State

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending March 6, 1909:

	Cases	Deaths
Tuberculosis Pulmonalis	464	163
Diphtheria	332	44
Measles	642	20
Scarlet Fever	352	23
Smallpox	—	—
Varicella	255	—
Typhoid Fever	28	7
Whooping Cough	62	3
Cerebrospinal Meningitis	8	7
Malarial Fever	—	—
Totals	2143	267

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending March 5, 1909:

SMALLPOX—UNITED STATES.

		CASES.	DEATHS.
California, Los Angeles	Feb. 6–13	3	..
District of Columbia, Washington	Feb. 13–20	1	..
Georgia, Cobb County	Jan. 16–Feb. 7	8	
Paulding County	Jan. 16–Feb. 7	15	
Illinois, Danville	Feb. 14–21	1	
Galesburg	Feb. 13–20	1	
Indiana, Elkhart	Feb. 13–20	1	
Evansville	Feb. 13–20	4	
Kansas, Kansas City	Feb. 13–20	6	
Topeka	Feb. 13–20	9	
Wichita	Feb. 13–20	1	
Kentucky, Covington	Feb. 13–20	1	1
Lexington	Feb. 13–20	3	
Paducah	Jan. 16–20	25	
Louisiana, New Orleans	Feb. 13–20	4	
Michigan, Grand Rapids	Feb. 13–20	1	
Saginaw	Jan. 30–Feb. 6	1	
	Feb. 13–20	2	
Minnesota, Minneapolis	Jan. 1–31	22	
Missouri, Kansas City	Feb 13–20	1	
St. Louis	Feb. 13–20	1	
Montana, Butte	Feb. 2–16	5	
Nebraska, Lincoln	Jan. 1–30	2	
North Carolina, Wilmington	Mar. 1	3	
Ohio, Cincinnati	Feb. 12–19	16	
Dayton	Feb. 13–20	1	
Tennessee, Memphis	Jan. 30–Feb. 13	55	
Nashville	Feb. 13–20	6	
Texas, El Paso	Feb. 9–23	3	
San Antonio	Jan. 24–31	15	..
Washington, Spokane	Feb. 16–13	1	Imported
Wisconsin, La Crosse	Feb. 13–20	7	..
Manitowoc	Feb. 13–20	1	..

SMALLPOX—FOREIGN.

Brazil, Bahia	Jan. 2–16	43	2
British Honduras, Stann Creek	Feb. 5–11	1	Imported
Canada, Halifax	Feb. 6–13	22	..
Chile, Talcaguano	Jan. 23–30	..	Present
Egypt, Cairo	Jan. 14–21	62	18
France, Marseille	Jan. 31	1	1
Great Britain, Bristol	Jan. 30–Feb. 6	7	..
London	Jan. 30–Feb. 6	1	..
India, Bombay	Jan. 19–26	..	10
Calcutta	Jan. 9–16	117	Epidemic
Madras	Jan. 16–22	..	1
Naples	Jan. 2–9	2	1
Indo-China, Saigon	Jan. 31–Feb. 7	9	..
Italy, General	Jan. 31–Feb. 7	25	5
Naples	Jan. 9–16	1	..
Japan, Formosa	Jan. 2–9	4	1
Batavia, Java	Jan. 9–16	1	..
Manchuria, Dalny	Jan. 16–23	..	4
Mexico, Acapulco	Jan. 18–24	..	2
Guadalajara	Feb. 6–11	..	24
Mexico City	Dec. 26–Jan. 2	..	1
Monterey	Feb. 7–14	..	Present
New Foundland, South Coast	Jan. 13	..	2
Norway, Bergen	Jan. 23–30	..	In lazaretto
Peru, Lima	Jan. 21	5	10
Russia, Moscow	Jan. 23–30	19	..
Odessa	Jan. 16–23	3	2
St. Petersburg	Jan. 16–23	9	..
Salvador, San Salvador	To Feb. 6	3	..
Santa Ana	To Feb. 6	40	14
Spain, Madrid	Jan. 1–31	..	4
Valencia	Jan. 23–30	3	
Turkey, Constantinople	Jan. 24–Feb. 7	..	

YELLOW FEVER.

Brazil, Bahia	Jan. 2–16	32	8
Para	Jan. 16–30	..	4
Dutch Guiana, Paramaribo	Jan. 1–31	11	1
Ecuador, Guayaquil	Jan. 23–30	..	2

SOME OBSERVATIONS ON NEPHRECTOMY, WITH A REPORT OF FIFTY-THREE PERSONAL OPERATIONS.*

By GEORGE EMERSON BREWER, M.D.,

NEW YORK.

ALTHOUGH to Simon is generally given the credit of the first nephrectomy, Watson in his treatise on genitourinary diseases calls attention to the fact that two Americans antidated the famous German surgeon in the performance of the operation.

In 1861 Walcott removed a carcinomatous kidney by the transperitoneal route from a woman fifty-eight years of age. Seven years later, in 1868, Peaslee, another American surgeon, performed the second transperitoneal nephrectomy. In 1869 Simon successfully removed a kidney by the lumbar route for the relief of a urinary fistula. One year later Gilmore, also an American surgeon, removed a kidney from a woman five months pregnant without interrupting the period of her gestation. It will thus be seen that of the first four nephrectomies on record three were performed by Americans.

It is only fair to state, however, that credit should be given to Simon for the first successful operation and also for the fact that his operation was undertaken after a thorough study of his case, and after a conclusive demonstration by animal experiments that one healthy kidney was sufficient for the needs of the economy.

In reviewing the history of all pioneer surgical work on important organs or diseased conditions, one finds as a rule that the earlier work was accompanied by a high rate of mortality. So high, in fact, that very few were willing to submit to the risk of surgical relief unless the condition in itself was desperate or the suffering intense. As time went on and more operations were performed, improved methods were devised, old difficulties were overcome and the results were correspondingly better. At a later period after a decade or two of accumulated experience the operative technic was so improved that the mortality was reduced to a point that patients in less dangerous condition gradually availed themselves of surgical relief which still further reduced the mortality and placed the operation on a firm therapeutic basis.

This sequence of events occurred noticeably in the surgery of the female pelvic organs, the vermiform appendix, the gall-bladder, the stomach, and to a certain extent also in the surgery of the brain and of the intrathoracic organs.

There is at present, however, a widespread impression that the majority of operations upon the kidney, and particularly the operation of nephrectomy, are to be regarded as dangerous procedures, and medical men are at times somewhat slow in referring to the surgeons patients presenting indications for these operations.

That this impression has in the past been well grounded is evident from the actual statistics stated in many groups of recorded cases. This high mortality, in the writer's opinion, is largely due to the fact that in the earlier days of kidney surgery only the most desperate conditions were brought to the surgeon for treatment, and also to the fact that until quite recently many surgeons have failed to avail themselves of the advantages furnished by the *x*-ray, cystoscopy, ureteral catheterization, examination of the separated urines, cryoscopy, the indigo-carmine, and phloridzin tests, in estimating the competence of the opposite organ.

The object of this communication is to demonstrate if possible that the old ideas regarding the danger of nephrectomy *per se* are exaggerated, and that with our modern methods of examination one can in suitable cases remove a kidney with comparatively little risk to the life of the patient.

Perhaps the best idea regarding the mortality following nephrectomy can be gained by a perusal of Von Schmieden's classical paper, which was published in the *Deutsche Zeitschrift für Chirurgie*, Vol. LXII, page 205. In this communication he gathered from all reliable sources statistics of the operation from Simon's nephrectomy in 1869 up to the year 1902. These he divided into three groups each representing practically a decade.

The first group comprised those cases reported up to 1880, when the pioneer work was being done, largely upon a desperate class of cases representing the terminal stages of renal infection and malignant disease. The second group comprised the cases between 1880 and 1890 during a period when the technique of the operation was largely improved. The third group was composed of the cases subsequent to 1890, a period when our present modern methods of investigating renal function were beginning to be employed.

Von Schmieden's report was based upon 1,118 cases of nephrectomy. His gross statistics, taking all the cases, were for the first decade a mortality of 50.6 per cent.; for the second, 34 per cent., and for the third, 17.4 per cent.

Three hundred and twenty-nine cases of malignant growth showed a death rate of 32.8 per cent., and only twenty cases could be found to be free from recurrence three years from the date of operation.

Of 201 nephrectomies for tuberculosis the mortality was 29.4 per cent.; of 124 cases of hydronephrosis, 18.5 per cent.; of 138 for pyonephrosis, 23.2 per cent.; of 108 for pyelonephritis, 33.3 per cent; of 47 for acute trauma, 17.9 per cent.; of 30 for urinary fistula, 17.0 per cent.; of 26 for cystic kidney, 30 per cent.; of 11 for solitary cysts, 36 per cent.; of 25

*Read before the Harvard Medical Society, January, 1909.

for floating kidney, 30.4 per cent.; of 24 for benign tumors, 12.5 per cent.; of 16 for unilateral hematuria, 18.7 per cent.; of 14 for echinococcus disease, 28 per cent.

It may be noted in passing that Von Schmieden's statistics confirm the view long held by the writer that the lumbar route is safer, and in the majority of instances a far easier procedure, than the abdominal approach; for in every class in which this point is mentioned the mortality of the lumbar operation is conspicuously less than the abdominal.

In the new growths, for instance, the mortality following the lumbar operation was 28 per cent.; that following the abdominal, 38 per cent.; in the tuberculous cases, 27 per cent. for the lumbar as against 42 per cent. for the abdominal; in pyelonephritis 31 per cent. for the former and 41 per cent. for the latter.

These statistics represent the entire period covered by the report. It is interesting to note that in practically every class a marked improvement was noticed in each succeeding decade. Thus taking the graver conditions, in the class of malignant growths the death rate, which was 64 per cent. in the first decade, was 43 per cent. in the second, and 22 per cent. in the last. In pyonephrosis it declined from 33.3 per cent. in the first to 15.3 per cent. in the third decade; and in pyelonephritis from 64.3 per cent. in the first to 16.7 per cent. in the third.

This brief résumé of Von Schmieden's statistics, while it conveys the impression of a great improvement in results in the thirty odd years since the beginning of renal surgery, leaves one with the impression that even six years ago the best available statistics for the operation as a whole showed the mortality to be in the neighborhood of 17 per cent.

That these statistics give an erroneous impression of the risks of the operation at the present day, the writer believes not alone from his own experience, but from the unpublished statistics of some of his professional colleagues.

Up to January 1, 1909, I have performed nephrectomy fifty-three times; of these fifty-one patients recovered and two died as a result of the operation, a mortality of 3.8 per cent. To avoid any misunderstanding regarding the meaning of the term recovered, permit me to state that with the exception of one patient recently operated upon, who is still in the hospital, every patient who recovered left his or her bed with a completely healed wound, with an actively functionating kidney on the opposite side, and was able to resume ordinary work or household duties.

The following are the various pathological conditions found in these fifty-three cases, many of the cases presenting two or more lesions: New growth, seven cases; tuberculosis, eight cases; pyonephrosis, eighteen cases; calculus, nineteen cases; septic infarcts, nine cases; hydronephrosis, four cases; pyelonephritis, three cases; hemorrhage, one case; necrosis of the organ from twisted pedicle, one case; urinary fistula, three cases; acute trauma, three cases.

I desire first to report the two fatal cases. The first of these occurred in a middle-aged man, upon whom nephrotomy was performed for the removal of multiple calculi of the right kidney pelvis. There was considerable laceration of the renal tissue in the removal of the four stones, giving rise to a severe hemorrhage, which was only controlled by generous gauze packing. Four hours later the hemorrhage recurred. I was summoned and performed a hasty nephrectomy on a moribund patient. Although the removal of the kidney was accomplished without more than a trifling loss of blood, and although the patient received a large intravenous infusion of physiological salt solution and was otherwise stimulated, he never rallied, and died at the end of four days from suppression of urine and edema of the lungs. Autopsy revealed chronic left-sided pyelonephritis and several calculi that had not been revealed by the *x*-rays.

This case occurred early in my experience at a time when we were just beginning to employ the *x*-rays; the urines were not separated, and to the best of my recollection the left side was not radiographed. Had either of these tests been properly carried out the condition of the opposite kidney would doubtless have been revealed, and I probably would not have removed the organ. As it was, I probably removed the only functionating kidney the man possessed. The procedure was undoubtedly an error of judgment on my part and probably would not have occurred at the present time.

The other death occurred in a feeble and profoundly prostrated girl, who had been suffering for weeks from pain, vomiting and septic intoxication. She had a movable tuberculous kidney, which had become adherent in the pelvic cavity, and had acquired a mixed infection. The operation was an exceedingly difficult one and was accompanied and followed by profound shock, which did not respond to active stimulating measures. I cannot blame myself for this fatality, as the difficulty in the operation consisted in exposing the kidney, it would scarcely have been less if only drainage had been employed, and it is exceedingly doubtful if simple drainage would have sufficiently relieved the grave toxemia to allow a secondary nephrectomy had she survived the primary operation.

Of the seven cases of new growth there were three of carcinoma, two of hypernephroma, one adenoma, and one large suppurating cyst probably echinococcus. All recovered from the operation. One of the carcinoma cases is still living and well eight years and eight months after the operation, the other two died of recurrence within two years. One case of advanced hypernephroma with lymph node metastasis in the neck and a complicating pyonephrosis died two months after operation, the other cases were well when last reported.

Of the eight nephrectomies for tuberculosis, one only died as a result of the operation, one other died two years after operation of general tuberculosis. All of the others were well or improving when last reported. It is an interesting fact that in two or three cases with moderate bladder involvement at the time of operation, a progressive improvement in the bladder symptoms occurred, and in at least one case complete absence of bacilli from the urine was noted at the end of two years, illustrating the well recognized fact that if the primary or chief tuberculosis lesion is removed, Nature often is able to cope with the remaining secondary deposits.

As my calculus cases have recently been analyzed and reported, I will not dwell upon this subject except to state that in my opinion a kidney containing one or more calculi, and also the seat of an advanced septic process should be removed if the opposite organ is healthy. To leave such a kidney is to invite subsequent trouble from recurrence of stone, pyonephrosis, or long continued sepsis.

It is also often safer to remove a kidney with

multiple calculi imbedded in its substance, than to inflict the trauma necessary to remove them, as alarming primary or secondary hemorrhage is apt to occur.

While no fatality occurred in my cases of pyonephrosis, pyelonephritis, septic infarcts, hydronephrosis, urinary fistula, hemorrhage, necrosis of the organ, or severe injury requiring removal, a few facts of clinical interest have been noted.

One frequently hears the advice, that in cases of acute renal suppuration, the kidney should at first be drained until the patient recovers sufficiently from the toxemia to bear the shock of a secondary nephrectomy.

While the advice may be wise in certain rare instances, as a general rule primary removal of a hopelessly diseased kidney will give better results, for in the writer's experience no operation in surgery can be more difficult or hazardous than the removal of a chronic suppurating kidney when surrounded by dense adhesions, as the following two cases will illustrate.

A man, aged 40 years, consulted the writer for the relief of a long standing urinary fistula of the right kidney. Several years before he had been operated upon for a calculous pyonephrosis. The wound had never healed and continued to secrete a moderate amount of purulent urine. Examined by a probe the presence of calculi was easily detected. Under ether anesthesia the kidney was exposed by a generous Koenig incision. On attempting to separate it from the surrounding structures it was found to be densely imbedded in a thick layer of connective tissue, evidently the changed fatty capsule, which was so adherent to the renal parenchyma as to absolutely preclude the possibility of manual separation. After a very laborious dissection, accompanied by a considerable loss of blood, the renal pelvis was reached. On attempting to lift the kidney upward to expose the vessels it was found that the vessels were so surrounded by dense cicatricial tissue that separation without rupture was impossible. As this firm fibrous exudate extended well over to the spinal column and did not allow the exposure of any part of the renal vessels, we strongly considered abandoning the operation. As the bleeding from innumerable sources on the separated adhesions was becoming alarming, I decided to secure the pedicle by a deeply placed purse string ligature of strong chronic gut around the vessels in the connective tissue bed. This was finally accomplished and when the knot was tied the kidney and afterwards the remaining part of the pelvis were cut away. The wound was partly united and packed with gauze. He made a slow but satisfactory convalescence.

The following case was without question the most difficult nephrectomy I ever encountered.

A boy, aged 20 years, was referred to the writer by Dr. W. H. Murray of Plainfield in August, 1908, suffering from a urinary fistula in the right inguinal region. Several months before this he had been operated upon for a supposed acute appendicitis. The operation was a difficult one and associated with considerable hemorrhage necessitating the use of numerous clamps, some of which were left temporarily in the wound. After rather a stormy convalescence urine was observed to flow from the wound in considerable quantity. One or two subsequent efforts were made to close the fistula but without result. On examination a scar of the previous operation was found in the right inguinal region, in the center of which was the opening of the fistulous tract which on probing was found to lead backward and toward the median line. Here on careful palpation there could be felt a mass which seemed to be a rather small malformed ectopic kidney.

Cystoscopy and ureteral catheterization by Dr. Osgood demonstrated normal urine from the left ureter. The ureteral catheter could only be passed a short distance into the right ureter, and from this no urine could be obtained.

Under ether anesthesia an incision was made to the outer side of the original scar dividing the several layers of muscle until the peritoneum was reached. This was slowly reflected from the iliac fossa until the outer edge of the misplaced kidney could be felt and seen. As a dense mass of adhesions now seemed to bind the skin and various intraperitoneal structures to the kidney, further attempts to expose it by this route seemed unwise, as the location of the vessels entering the organ could not be determined. The peritoneal cavity was next opened by a median incision and the free intestines packed off with large masses of handkerchief gauze It was then found that the cecum and several adherent loops of small intestine apparently surrounded the fistulous tract. A median incision was next made in the parietal peritoneum covering the great vessels and this was gently reflected from the median line until the kidney was finally exposed. Several large vessels were seen passing from the aorta and right iliac vessels to a cleft on the anterior surface of the kidney. These were secured and divided. After this with one hand in the external wound, and the other in the median incision, the kidney was with great difficulty separated from the overlying adherent intestines and removed. The parietal peritoneum was then replaced and sutured, both wounds were united by layer suture and the fistulous tract packed with formalin gauze.

His convalescence was prompt and uneventful.

Eight cases of acute septic infarcts of the kidney were treated by nephrectomy without fatality.

As the writer has already called attention to this type of renal infection in previous papers, and discussed the relationship between it and the other gross forms of kidney suppuration, I will mention but a single instance which will serve to illustrate the type.

A woman, aged 22 years, experienced a severe pain in the epigastrium and right side of the abdomen, with vomiting and high fever. She was sent to the Roosevelt Hospital with a diagnosis of acute appendicitis. On examination, the appendiceal region was free from evidences of inflammation There were, however, pain and muscular rigidity in the right hypochondriac region, with tender points over the gall-bladder and in the costovertebral angle Temperature, 105° F.; pulse, 120; leucocytes, 18,000 Cystoscopic examination was negative; urine from the right kidney scanty and slightly albuminous, a few pus and blood cells, that from the left kidney was abundant and apparently normal. Widal negative; no plasmodia; no tubercle bacilli in the urine The diagnosis rested between an acute infection of the gall-bladder or the kidney.

Small anterior incision, gall-bladder, and liver, found to be normal, but the right kidney seemed to be enlarged. Anterior incision united and the kidney exposed by lumbar route. The perinephric fatty tissue was edematous; the kidney enlarged highly congested and the seat of innumerable small in

farcts. Nephrectomy was performed. After operation the temperature fell from 105.5° F. to 97° F. within twelve hours and thereafter remained practically normal. The patient made a satisfactory convalescence. Microscopic examination of the specimen showed it to be filled with minute embolic abscesses. One year later this patient married and became pregnant. I had an opportunity of examining her urine before and after her confinement. It was normal in every respect. Her confinement was normal, and she presented the picture of robust health two months later.

A single case of gangrene of the kidney has fallen under the writer's observation.

A married woman, aged 40 years, suffered for two months from right-sided renal colic, with vomiting and pyuria. An exploratory operation was done by another surgeon. The kidney was delivered through a lumbar incision, and carefully examined for stone and other lesions. As the examination proved negative, the kidney was replaced and anchored by catgut sutures. Considerable pain followed the operation, with fever, vomiting, and great tenderness. These symptoms increased in severity, and the general condition became alarming. The wound was therefore reopened and the kidney found to be completely necrotic, evidently from strangulation of the vessels due to a twisting of the pedicle, the kidney having been replaced at the first operation in an inverted position, with the lower pole uppermost. The necrotic kidney was removed and the patient made a satisfactory recovery.

As an example of a traumatic case the following will be of interest:

Colored man, aged 28, fell from a height injuring his left side and abdomen. Hematuria immediately after injury; second specimen of urine clear. Complained of pain and soreness in left flank; moderate tenderness and slight fullness; no shock. Several hours later complained of sharp abdominal pain, vomited and became restless and thirsty. Second examination showed abdominal muscles rigid, free fluid in peritoneal cavity and increased fullness in left flank. Pulse 120, temperature 101°. Under ether anesthesia the abdomen was opened and found full of fluid and clotted blood, stomach, intestines, liver, and spleen examined with negative result. Abdominal cavity thoroughly irrigated with hot salt solution and wound closed. Patient's condition became alarming and an intravenous saline infusion was given, also strychnine and other stimulants. Left kidney exposed by lumbar incision found to be divided by two transverse ruptures into three unequal portions, one of which lay free in the large collection of fluid and clotted blood, the other two were attached to the vessels forming the pedicle. The pedicle was clamped, the renal tissue hastily removed and the wound packed. Slow recovery from shock; no febrile reaction. Pedicle clamp removed on the eleventh day. Recovery.

In conclusion I desire to state that this series includes every case of nephrectomy upon which I have personally operated and that no effort has been made to select favorable cases. Every case seeking advice and presenting clear indications for the operation has been advised to submit to operative treatment. A fairly large number of these operations was performed before our present more refined methods of examination had come into vogue, and where we were obliged to depend upon the history and the results of an ordinary physical examination for data regarding the functional activity of the other kidney.

I feel confident that had we been able to carry out methods which we now habitually employ, only one death would have occurred in the series.

CASES ILLUSTRATING THE RESULTS OF THE SO-CALLED HEATH OPERATION.*

By S. MACCUEN SMITH, M.D.,

PHILADELPHIA.

The fact that the various professional periodicals, especially those devoted exclusively to diseases of the ear, nose, and throat, contain so many papers repeatedly describing the various surgical procedures for the relief of aural disease is proof positive that this branch of surgery is still an art, and has not yet assumed the dignity of a science; and yet it is only by repetition and investigation that we finally arrive at certain conclusions which embody the best that the present age has contributed. In other words, it is through the recording of our various mistakes and numerous failures that we are enabled to distinguish between the right and the wrong, and thereby to receive the stimulus of such recognition for better and more accurate work. This is true in point of diagnosis as well as in the improvement manifested in various surgical procedures for the relief of pathologic conditions involving the organ of hearing.

The evolution of operative otology from the time when the first imperfect simple mastoid operation was performed, consisting of little more than boring a hole through the cortex, up to the time when Schwartze, Stacke, and others devised the comparatively perfect radical operation, has shown great strides in a procedure calculated to save the lives of thousands, and in this respect is scarcely secondary to the great boon conferred upon suffering humanity when the operation for appendicitis was first devised.

In the very recent past we have heard much of what might be expected of the so-called Heath operation, especially in its relation to the preservation of hearing. If this procedure, under whatever name it may appear, will succeed in relieving dangerous pathological processes in the tympanic and accessory cavities, and at the same time insure not only the preservation but the actual improvement of the hearing power, the further evolution of aural surgery has certainly had a tremendous impetus.

On general principles it is difficult for one to accept as good surgical procedure that which advocates the non-disturbance of necrotic tissues, be it either diseased ossicles or carious bone that must necessarily remain in the narrow space connecting the tympanic cavity with the mastoid antrum, and yet this is precisely what is claimed for the Heath operation. In other words, we aim to perform a radical operation, which includes the complete exenteration of the cells comprising the temporal bone, with the exception of the tympanic ring and the fragment of ossicles and membrana tympani which are left undisturbed, as the extent of their necrotic involvement seems to make but little difference in the final result. In my limited experience some of the more extensive necrotic cases have made the very best recoveries, both in the way of entire ces-

*Read before the Eastern Section of the American Laryngological, Rhinological, and Otological Society, at Philadelphia, Pa., January 9, 1909.

sation of discharge and in more or less complete regeneration of the membrana tympani, while the ultimate restoration of hearing power has been carried to almost normal. On the other hand, I have to report that in some cases of shorter standing, where the necrosis seemed to be limited, I was unable to arrest the otorrhea, due, probably, to my faulty technique; nevertheless, the hearing distance was greatly increased.

In some patients, where to all appearances not even a fragment of drumhead and ossicles remained, the removal of the inflammatory débris within the mastoid antrum, tympanic cavity, and aditus, preserving intact the annulus tympanicus, has certainly been the means of arresting a chronic discharge and greatly improving the hearing, without, however, causing a regeneration of the membrana tympani. The principal contention of Heath, therefore, that the mastoid antrum is more frequently the site of a continued suppuration, rather than the cavity of the middle ear, would seem to be substantiated. Such being the case, we can readily realize how easily the narrow, unyielding aditus may become obstructed by pathological débris, causing the antrum to fill with inflammatory products, this in turn producing a degree of pressure which may extend upward into the middle fossa, downward into the mastoid process and backward toward the lateral sinus.

In the past few years excision of the membrana tympani and ossicles, instead of the usual mastoid operation, has been revived and strongly urged, with a view of curing certain cases of chronic discharging ears. We have felt it our duty, in certain instances, to advise this operation, with a view of arresting the discharge. Obviously, all of us have frequently been disappointed in the results, no doubt owing to the aforementioned fact that the principal site of the trouble, being located in the antrum, was not reached by an excision of the ossicles, and the operation did not even provide for drainage through an obstructed aditus, which omission in the end compelled us to resort to the usual radical procedure. My more recent experience, therefore, teaches me that the Heath operation, for the reasons above mentioned, will largely supplant that of the excision of the ossicles for the cure of an otorrhea.

I have performed the Heath operation in some cases of acute mastoiditis with extensive bone necrosis, where, owing to the great destruction, I should otherwise have felt obliged to perform the usual radical operation. This was especially true in cases where extensive erosion had destroyed the greater part of the bony external auditory canal, the discharge from the antrum and cells escaping through this opening.

In another class of cases I believe this operation to be of the greatest importance. We all see cases of chronic otorrhea in children involving both ears, where the hearing is practically normal. Some of these cases are persistently unyielding to any line of treatment other than operative. The simple mastoid operation does not relieve the discharge, and in performing the radical operation there is great danger of interfering with audition. If such a condition were present in only one ear in a young child, the gravity of one-sided deafness would not be so great; but suppose we should perform a radical operation on both ears of a child for the relief of an otorrhea. There is almost a certainty that the hearing will be greatly interfered with, which condition is likely to grow worse. In this event the child, if young, will in all probability become dumb as well as deaf. Even though the aural disease may endanger the child's life, the responsibility of advising a double radical mastoid operation, in view of the possible danger to the hearing power and the consequent loss of speech that may follow, should not be lightly assumed by any surgeon. Another point in favor of this modified operation is that there is less liability of injuring the tympanic branch of the facial nerve, but the most important benefit to be derived from this surgical procedure is the eradication of the danger zone, which is located in the antrum, thus removing the source of a disease most prone to cause intracranial complications.

There are in attendance for your inspection about a dozen cases showing the results of the operation for the relief of the various forms of suppuration, and detailed histories of five of these cases follow:

Case I.—Dr. C. S. H., male, white, age 29 years. Presented himself for treatment on April 1, 1908.

History.—Eighteen years ago he contracted a suppurative otitis media of the right ear, which has continued to date. Ten years ago the membrana tympani and ossicles were excised with a view of relieving the otorrhea. This very materially lessened the quantity of the discharge, but it never entirely ceased. For the past year the patient has complained of increasing nausea and vertigo, both in frequency and severity, the continuation of which caused him to seek relief through operative interference.

Examination.—Right ear shows the absence of the membrana tympani and ossicles. The canal is well filled with a non-offensive, yellow, purulent discharge. The roof of the tympanic cavity has been absorbed through carious erosion, exposing the dura.

Operation.—The Heath operation was performed on April 6, 1908. The cortex looked entirely healthy, the entire process having undergoine sclerotic changes, being, therefore, quite filled with new bone formation and exceedingly hard. No actual disease of the bone was noted until the antrum was reached, and at this point we found considerable granulation tissue and the exposed dura above mentioned. The patient made an uninterrupted recovery, the discharge having ceased in six weeks from the date of operation and the membrana tympani regenerating in about the same time. The hearing, although not in any sense acute, has improved considerably. The chief point of interest here, however, as in some other cases, is from the fact that the discharge has entirely ceased and there is a regeneration of the membrana tympani. The patient's general health has improved considerably, he weighing more than at any time in his life.

Case II.—H. O., male, white, age 16 years. Came to Jefferson Hospital Clinic for treatment on July 23, 1908.

History.—The patient gives a history of having suffered about nine years ago from a suppurative otitis media. It is uncertain, however, how long this continued. The present attack of otitis dates back about two weeks, the patient apparently suffering the usual amount of pain incident to such a condition.

Examination.—The canal of the left ear is filled with a yellowish discharge, offensive in character and streaked with blood. The membrana tympani is largely destroyed, very red and edematous, the inflammation involving the osseous external auditory canal, which bleeds freely on the slightest irritation

from a cotton covered probe. I have no note of the exact condition of the ossicles at this time. The boy hears the tuning fork at about three inches, aerial conduction. Ordinary conversation can be heard only in close proximity to the ear.

Treatment.—The patient was provided with an antiseptic solution for irrigation, returning to the hospital September 29, or about two months later. The examination at this time showed the discharge to be of the same character. There was not at any time during the course of his disease pain over or in the region of the mastoid process, not even on deep pressure. A skiagraph of the mastoid was taken and portrayed the process as well filled with pathological débris.

Operation.—The Heath operation was advised and performed on October 16, or after three months of continuous discharge following the last attack. A separation of the soft parts showed the cortex to be rather hard, but bleeding at several points. The interior of the mastoid process was well filled with granulation tissue and extensively necrotic. There was not, however, very much free pus found. The operation consisted of the complete exenteration of the cells. The patient states that about one month after the operation he began to notice some improvement of hearing. The membrana tympani has regenerated with the exception of a small pear-shaped opening in the posterior part. The hearing has materially improved. The boy now hears the tuning fork at about eight inches and ordinary conversation at from six to eight feet.

Case III.—M. W., male, white, age 42 years. Patient first appeared before me on October 12, 1907.

History.—About four years ago, while swimming, he contracted an acute suppurative otitis media of the right ear. The discharge has continued to date. The patient claims that the attack occurred without pain and that he was entirely free from suffering of any kind until about four weeks before seeking treatment, or about three years and ten or eleven months after the initial attack, at which time he began to have pain in the ear, especially over the mastoid process, which was aggravated by pressure or percussion. The patient also states that this pain was considerably increased by bending forward. The only treatment he has received up to the present time has consisted of syringing the ear with salt water.

Examination.—An examination shows the discharge to be copious, greenish-yellow in character, and very offensive. There is destruction of the lower two-thirds of the membrana tympani, Shrapnell's membrane being intact. The ossicles and landmarks are entirely obliterated on account of the swelling, and there is considerable granulation tissue in the tympanic cavity. No marked bulging of the superior and posterior wall of the external auditory canal is present. There is, however, rather marked tenderness on moderate pressure over the mastoid process, more especially pronounced at the tip. The patient hears only when spoken to very distinctly and in a loud voice. Tuning fork is not heard by aerial conduction. Bone conduction, however, appears to be fairly good.

Operation.—The Heath operation was performed on October 25, 1907. The patient noticed a considerable improvement in hearing about two weeks after the operation. This improvement was progressive for about four months, he retaining this increased hearing power at the present time.

Examination, January 2, 1909.—The membrana tympani in this case has never regenerated. The discharge, however, has entirely ceased. The fragment of malleus and also that of Shrapnell's membrane remain about as they were before the operation. The hearing power, according to the patient's statement, assumes that of almost normal. Hears tuning fork at about four inches and a low voice at about five or six feet.

Case IV.—E. S., female, white, age 11 years. Presented herself at the Jefferson Hospital Clinic for treatment on November 10, 1908.

History.—Eight years ago, without known cause, she contracted an acute suppurative otitis media of the left ear, which has continued recurrently to date. The mother states that the discharge is usually less during the warm weather.

Examination.—Examination shows the canal well filled with thick, yellowish pus, without any particular odor. The membrana tympani is practically destroyed except Shrapnell's membrane. There is marked redness and some edema of the external auditory canal, especially the superior and posterior part adjacent to the tympanic ring. There is no pain over the mastoid, even on deep pressure. The child has great difficulty in hearing at school, it being necessary to place her near the teacher so she can properly receive instruction.

Operation.—The Heath operation was performed on November 17, 1908. The exposed cortex was found to be practically normal in appearance, but unusually hard and thick. The entire mastoid cells, however, were necrotic, which required their complete removal. The sinus was more superficial than normal and pushed far forward. Six days after the operation the patient was discharged from the hospital and returned to the Out-Patient Department for the usual dressings. The mother feels that the hearing has gradually improved somewhat, although she lacks the marked improvement that is shown by some of the other patients. The discharge, however, has entirely ceased and the membrana tympani has regenerated.

Case V.—H. D., male, white, age 18 years. Came to Jefferson Hospital Clinic on October 11, 1907.

History.—Family history good. Only disease from which patient has suffered is whooping cough, which is said not to have had any influence on the aural disease. Has suffered from a recurrent suppurative otitis media of the right ear from infancy, the trouble recurring at intervals ever since. Pain is worse during the period of cessation of discharge. The last exacerbation occurred about two years ago, causing severe suffering. The discharge continued uninterruptedly until patient came to the clinic. With each acute exacerbation the patient becomes quite ill, and before the appearance of the discharge suffers from high fever, nausea and vomiting, severe headache and great prostration. The hearing power is very much impaired, the patient involuntarily turning the good ear toward the speaker, feeling that the right ear is more or less useless for ordinary conversation.

Examination.—Examination at this time revealed a discharge in the external auditory canal, the greater part of the membrana tympani being destroyed. The history of the case does not define the character of the secretion nor state definitely as to the presence of granulation tissue in the tympanic cavity. Deep pressure over the mastoid process elicited some tenderness.

Operation.—The Heath operation was performed

on December 6, 1907. The mastoid process was found to be of the diploic variety, the accompanying osteomyelitis extending backward beyond the mastoid bone. The cells were extensively necrotic, the carious erosion exposing the sinus for almost its entire length. The boy was entirely well about six weeks following the operation; that is, the discharge had ceased, there was a complete regeneration of the membrana tympani and the hearing power had improved almost to normal, the patient reporting that he was free from all discomfort.

Examination on January 2, 1909.—Improvement has continued uninterruptedly, and if anything there is still further betterment in hearing and the entire absence of any discharge. Hears ordinary conversation at from twelve to fifteen feet.

Notwithstanding the fact that the results seem to justify this surgical procedure in certain cases, yet it is most difficult to reconcile myself to the belief that it is sound operative technique to deliberately retain pathologic products, however minute, within the organ of hearing. However, as you will see from the cases present for your examination, the results generally are good and in some instances brilliant. Therefore, the manifest betterment of the aural condition of the patients compels us to give some recognition to this procedure, and at the same time serves to stimulate us to still further investigation.

Generally speaking, the operation should not be performed in the presence of suppurative or necrotic diseases of the labyrinth, where cholesteatomata are present within the cavities of the tympanum or antrum, or abscess formations involving the interior of the skull, especially if the infection gains entrance through the tegmen tympani.

On the other hand, we would feel inclined to advise the operation in appropriate cases, from the fact that it does not interfere with the membrana tympani and ossicles, thereby not jeopardizing the power of hearing. It would seem best, as a rule, for this reason, that the operation be performed early, before the disease has caused much destruction of the conducting apparatus. Some other points in its favor are that the danger of injury to the facial nerve is very much reduced: the shock from the surgical procedure is considerably lessened, and the recovery is notably quick, while at the same time it corrects the pathologic process within the danger zone, the antrum.

This procedure, furthermore, not only preserves the hearing present at the time of operation, but actually improves it to a noticeable degree in the majority of cases. Then, again, it is suitable in both the acute and chronic variety of cases, and will probably supplant the operation known as ossiculectomy for the cure of an otorrhea.

THE HYGIENIC AND CLIMATIC PROPHYLAXIS OF TUBERCULOSIS IN CHILDHOOD*

By FREDERICK L. WACHENHEIM, A.B., M.D.,

NEW YORK.

The higher aims of medical science seek prevention rather than cure. In combating tuberculosis, which so often begins in infancy, blights the fair promise of childhood and adolescence, usually terminates in premature death, and imposes a tremendous economic burden on the community, our energies must needs turn to an efficient prophylaxis. As our knowledge of the etiology and pathology of tuberculosis has increased, it has become more and more evident that this prophylaxis must be begun early, in infancy and childhood. The subject of the prevention of tuberculosis in its entirety is far too vast for discussion in one short paper; those portions that relate to public hygiene in its manifold aspects have been disposed of by other members of this Congress. I shall therefore deal here only with such matters as relate to personal hygiene, including the general regimen of life and the choice of residence, the last considered essentially as regards the elements of climate.

Good general nutrition has always been considered one of the best preventives of tuberculosis. This is so far true that a loss of weight invariably accompanies a progressive state of this disease, but is of course not true of the converse. It is also a common fallacy, especially in our sanatoria, to consider an increase in weight a sign of improvement, whereas it is not difficult to fatten any patient who is not rapidly or at least progressively going down hill, by enforcing a quiet life and supplying an ample dietary. Nevertheless, we may regard a reasonable amount of adipose tissue as an indication of some individual resistance to the tubercle bacillus; children, especially, who suffer from what we call scrofulosis, that either is a marked susceptibility to tuberculosis or the presence of one of its chronic forms, regularly improve if we can make them gain in weight.

Our greatest difficulty is with children who suffer from anorexia, which may be a sign of tuberculosis already established or, on the other hand, merely the manifestation of a neurosis or a perverted metabolism, or due to vicious habits of eating or to dental caries. In these cases we must begin by recollecting any one or more of the latter conditions that may be present, paying particular attention to the candy and caffeine habits and to painful teeth. Neurotic children must not be permitted to associate with older or over-strenuous companions and should be guarded against nervous excitement; sound sleep should also be seen to. Overwork at school is uncommon nowadays, but too many children sit at home reading when they should be out of doors. An out-door life may sometimes be secured most readily by moving from the city to the suburbs, to a milder and sunnier climate, or to the more bracing conditions at the seaside or in the mountains: I shall discuss this more fully later on. The chronic constipation that regularly accompanies the anorexia of children is usually only concomitant, but may sometimes call for special treatment.

The diet of children should be as varied as possible, with the avoidance of high seasoning and stimulants of every kind, including tea and coffee. Eggs and cereals, bread, and plenty of good butter and milk should form the basis of the three or four daily meals; meat should be given only once a day to young children, not more than twice even at puberty. Treatment with fats, especially the distasteful cod-liver oil, is not regarded with so much reverence as formerly; I have already explained that mere fatness is not necessarily a sign of robustness. Nevertheless, cream and butter in moderate quantity are usually relished by children, though not liked by some; a few learn to enjoy a reasonable amount of pure olive oil. These fats are all

*Read by title at the International Congress on Tuberculosis, October 1, 1908.

relatively digestible and free from the disgusting odor and taste of cod-liver oil, which is also said to be becoming scarce and frequently substituted by other and still more unpleasant fish oils. In any case, we must remember that fats are useful, especially during the colder months, in furnishing caloric value in its most concentrated form. The carbohydrates may be given freely, and I do not share the common prejudice against sugar, which is, after all, but the equivalent of an equal weight of starch. The only objection to large amounts of cane sugar is that they spoil the child, leading it to desire all its food highly sweetened and develop the candy habit, pernicious chiefly because of the inferior quality of sweets usually purchased, but also because of the secondary development of the chocolate habit, which is merely a variation of the reliance on coffee or tea as a stimulant. Excessive fondness for sugar must be combated by withholding that article of food until the child learns to do without it, or by narrowly restricting its quantity. I must not forget to mention that the oxybutyric acidosis, so often observed in children, is probably not caused by the excessive ingestion of carbohydrates. Since we know that this intoxication, in diabetics, is due to a too strict withdrawal of carbohydrates and an excess of fat and albumin in the diet, we may safely conclude that in children, also, this affection is the result of an excess of fatty or proteid, not carbohydrate food.

Nothing is so useful to stimulate the appetite of children as exercise, if care be taken not to push it to exhaustion in which the digestive apparatus will inevitably share. Exercise, including systematic gymnastics, is also in high repute as a prophylactic against tuberculosis, but it is as well to subject this purely empirical view to scientific revision. There is, of course, no doubt that good muscular development is a useful personal asset to one whose vocation in later life calls for great physical strength. Otherwise the assiduous cultivation of gigantic muscles, which is quite possible to every one of us under scientific management, has little permanent value; the painfully acquired hypertrophy disappears rapidly from disuse, when heavy work is discontinued. I do not think that I am going too far when I call this sort of gymnastics a sheer waste of time, and I may go even further, pointing to the circumstance that physical overexertion, especially if long continued, is one of the immediate causes of premature arteriosclerosis, and likely to be associated with at least periodic albuminuria. It might be argued that this phase of the subject hardly concerns us here. What is more to the point is that careful observation seems to show an increased susceptibility to tuberculosis among record holding school and college athletes[1]; it is evident that the exhaustion following their strenuous competitions favors the invasion of disease; athletics of this type should absolutely be forbidden to school children. It is therefore to be regretted that efforts are now actively under way to foster interscholastic contests; they are unquestionably harmful physically, and seem to be even more pernicious morally, if we may judge by recent developments in so-called amateur sporting circles. It seems to me that our higher institutions are acting wisely in trying to limit the field of competitive athletics; it is a pity that the secondary schools are endeavoring to extend it.

Personally, I have no hesitation in declaring that I see no value in athletics save for the outdoor life they involve; from this point of view the less strenuous games, especially those in which the vain desire to break records plays no part, are to be preferred to mere feats of strength, speed, and endurance. We can safely favor such sports as tennis and baseball, which train the eye and brain as well as the muscles, which may be discontinued when the child feels tired, and whose rules set a time limit of a few hours. Indoor games and gymnastics are far inferior, and only to be resorted to for special purposes, when bad weather interferes with life out of doors; in winter snow and ice afford opportunities for wholesome sport that cannot be replaced by the best gymnastic apparatus. In orthopedic practice it is regularly found that gymnastic exercises are most needed by such children as have lived too much indoors; those who have led an active outdoor life have no occasion to resort to dumbbells or Indian clubs.

I may be criticized for having treated exercise merely as a means of hardening, and accept the criticism cheerfully. For me the sound body is merely the abode of the sound mind, physical prowess alone being of little moment in our day and steadily growing less. If we fortify the physique against that arch enemy of early life, tuberculosis, we give the brain a chance to win for its owner a position in the world to which mere muscle will hardly serve to raise him.

Having brought up the term "hardening," it will be worth while to discuss this form of training a little more fully. It has long been, and still is, regarded as our mainstay in combating a tendency to tuberculous infection, or as an aid in resisting the further inroads of an infection already acquired, but for the time being latent or quiescent. It is much to be regretted that the recent brilliant investigations bearing on the doctrine of immunity, with all their absorbing interest and eventual possibilities, as yet throw no light on the merits of hardening as a therapeutic method. Nevertheless, its value in the treatment of established and evident tuberculosis has been placed beyond question, and, despite its empirical status, it will remain for the present also our most valuable prophylactic agent.

To attempt an exact definition of hardening merely begs the question. The degree of hardening sought has hitherto varied according to the mental attitude of the individual clinician, for the physiological data that should aid us in reducing this procedure to some sort of system are lamentably incomplete. The theory of catching cold is one of the most actively mooted points of pathology, even if we define a cold as an acute infection of the respiratory tract. Many utterly deny that a sudden chilling of the body can cause a cold; only a few accept the exposure etiology *in toto;* most of us handle it with reservation as not proven. Though an advocate of this view, I admit that the evidence in its favor is very inconclusive. Furthermore, the question whether a cold predisposes to tuberculous infection is quite unsettled, but I believe that the invasion of the tubercle bacillus is undoubtedly favored by a previous infection of the respiratory tract, as happens, for example, after an attack of measles. Thirdly, the amount of protection that hardening affords against acute respiratory disease is still in dispute, and the same may be said concerning the degree of hardening that should yield the best results. Hecker,[2] in an interesting article, has indeed proved that excessive hardening predisposes to colds, but no one has furnished really satisfactory evidence that moderate hardening assists the organ-

ism in acquiring even relative immunity. As to this last point, we are still on an entirely empirical basis; all that we know is that experience shows moderate hardening to be a means of defence against tuberculosis, and excessive hardening, so called, to be no hardening at all, but a most effective method of lowering the general resistance to infection of the respiratory tract with the organisms that cause acute inflammation and probably tuberculosis as well.

It is evident that we cannot draw the line between reasonable and excessive measures of hardening arbitrarily, nor can any sweeping rule be laid down to guide us, unless we take our departure from the standpoint of conservatism. Our idea should be to start with a minimum, and to work up to a higher degree gradually, taking care to keep within the range of tolerance of the particular individual before us. We may, however, regard two points as settled: First, that the patient most urgently requiring hardening should be handled with especial gentleness at the outset; secondly, that hardening should be less and less strenuous as we depart from the age of thirty or forty years, in either direction, so that infancy and old age should be subjected to the mildest measures only. These two principles depend on the well-known physiological fact that the efficiency of the thermoregulatory apparatus of the body varies according to age and individual robustness; to reduce them to a practical basis it will be necessary to adopt the working formula which, on a previous occasion,[3] I have elaborated as the theory of the indifferent temperature. As this designation may still be somewhat unfamiliar, I may be pardoned for dwelling on it again in detail.

By the term "indifferent temperature" we may designate that atmospheric warmth at which the thermoregulatory apparatus of the body is at rest, the animal heat being maintained by the minimum normal respiratory activity alone. Both heat and cold act as stimulants, though in different ways. Heat can be counteracted only by the vasodilator apparatus; this naturally becomes exhausted in the course of time, producing the condition called enervation. Cold may be combated either through the vasoconstrictor mechanism or through muscular exertion, of which the latter may be controlled voluntarily; in addition, we have the auxiliary means of clothing and artificial heat, so that our physiological resources need not be overtaxed. To demonstrate that, properly regulated, either heat or cold may be employed as a tonic, I need only refer to the Japanese custom of hot bathing; it seems, indeed, as if their method were preferable in some ways to our cold baths, for it involves no risk of chilling the overheated body surface. As to the ultimate hardening result, the Japanese laborer certainly leaves nothing to be desired in that respect.

The hot bath is, however, the only means of employing heat as a hardening method that can be regulated for general use; the employment of cold is far more available, since our climate supplies sufficiently cool air during the greater part of the year, so that mere life out of doors may be effectively utilized. Cold water is quite readily obtainable at all seasons. It is for these reasons, perhaps, that European and American methods of hardening resort to the application of cold exclusively.

We are now fortunately, as I think, entering on a period of reaction from the mania for violent hardening of a few years ago, when the most popular measures amounted to positive cruelty. I need only recall that young children, even infants, preferably those that appeared delicate, were plunged into cold water two or three times a day, and that nudity to the limit of the law was regarded with favor. Going about barefoot indoors at all seasons, and as little clothing on the extremities as possible out of doors in summer, are still widely advocated, the great object evidently being to keep the child uncomfortably cold all the time. In spite of the absurd extremes mentioned, however, the general principles of hardening still hold good, provided the measures applied are kept within rational bounds; I may, therefore, at this point give a brief outline of such methods as seem to me reasonable and adequate, neither pampering and enervating the children, nor on the other hand, exposing them to unnecessary discomfort and risk.

Children should, of course, be out of doors as much as possible; this sounds axiomatic, but is not so easy to carry out in the more congested city wards, especially among the poor, where the mother's manifold household duties keep her and her family at home nearly all day. Thus I see many instances where promising infants gradually fall below par, merely because they are taken out only once or twice a week even in pleasant weather. In this connection we may note with interest the observations of Hansemann[4], which I have been abundantly able to verify. Without ignoring the harmful effects of artificial feeding, he attributes rickets chiefly to what he aptly calls imperfect domestication; in other words, he considers man still imperfectly adapted to an indoor life, and regards that form of malnutrition which we call rhachitis as due to insufficient fresh air and sunlight. I might add that many obscure forms of anemia are also unquestionably caused by living in the semi-darkness of many of our city rooms; similar conditions once were common in prisons, and may still be observed in miners. It seems that children, as well as plants and most of the lower animals, thrive to perfection only out of doors. It also seems that the rhachitic and anemic children are more subject to tuberculosis than such as are more robust; it is certain that many of them acquire a chronic or latent tuberculous infection in very early life, as we cannot otherwise account for the relative frequency of glandular enlargements in this group.

During the first month of infancy the thermoregulatory apparatus of the body still functionates very imperfectly, so that exposure to cold easily reduces the temperature below normal; this condition has been shown by experience even more than experiment to favor the development of acute respiratory or gastrointestinal disease. Newborn infants must, therefore, be kept indoors, save that an outing may be permitted in the third or fourth week in midsummer weather. After the first month of life the baby's first outing depends on the season of the year; it is well to remember that the first airing requires a temperature of at least 70° F. (21° C.), with calm and sunny weather. Later on, of course, a lower temperature will suffice, but it is evident that a baby born at the beginning of the winter may have to be kept indoors for months, if its native climate be cold or damp. Toward the end of the first year low temperatures may be largely disregarded; our very cold days—I am speaking of the middle Atlantic coast—are nearly always sunny, though sometimes windy, so that the infant may be stationed on the sunlit eastern or southern side of a building during the forenoon, thereby being sheltered from our keen northwest winds. Under these con-

ditions a temperature well below the freezing point is easily borne. I have seen infants in their second half year, well bundled up, basking in the sun on some of our most severe days, in evident comfort. The rule, occasionally laid down, to keep infants indoors when the temperature falls below 20° F. (—7° C.), need not be so strictly adhered to; it involves practically imprisonment far northward, but exposure to relatively severe cold in the South. We must not forget that 40° F. (4° C.) seem as cold at New Orleans as zero (—18° C.) at Montreal, because the normal winter temperatures are, respectively, 15° (8° C.) higher; sensitiveness to cold is largely a relative matter, depending on what we have become habituated to. It is a case where sound judgment will be a better guide than any formulated rule.

After the age of two years mere cold may be disregarded altogether, whereas dampness and high winds are still harmful; toward the school age children should be kept at home only when it rains, a dry and cold snowstorm being relatively unobjectionable.

I must not fail, in this connection, to animadvert briefly on the so-called house airing, frequently recommended to timid parents as a substitute for outdoor life; as a matter of fact, it is not even a poor imitation thereof, but, on the contrary, a measure replete with danger. I need only recall that the child is exposed to a cold draught at every inadvertent opening of the door; conditions are entirely different on a veranda or in an open tent, where there are no considerable contrasts of temperature and the air currents are diffused. I shall also add a few words of condemnation for the solarium, referring only to its close resemblance to the gardener's hothouse; hardening may often become irrationally excessive, but hothouse treatment is absolutely indefensible in dealing with healthy children.

When the child's native climate, in combination with individual lack of robustness, prevents the enjoyment of any great measure of outdoor life, a change of air is indicated. As we rarely need to resort to climatic hardening in the first few months of life, the very warm resorts do not greatly concern us. Infants past the age of three months do not require an afternoon temperature averaging more than 65° F. (18° C.), corresponding to that of Boston or New York in May; this figure may be obtained in midwinter in Northern Florida, Southern California, the lowlands of Arizona, and Egypt. Children who are beginning to run about do better at a temperature some ten degrees (6° C.) lower, for there is no method of hardening that can compare to exposure to a moderately bracing climate. The conditions just stated are obtainable in winter in the Carolina lowlands, Northern Georgia, Middle California, Southern Italy, and the Riviera. All these regions afford ideal conditions for young infants in early spring, for it is inadvisable to take a baby that has wintered in the South to such a climate as Cincinnati or Philadelphia before mid-April, or to Chicago or Boston before May; the change from warm sunshine to chilly dampness involves great risk. All the districts so far mentioned have from 50 to 70 per cent. of sunshine during the Winter months, much irregularity of temperature in the Southeastern States, a great difference between day and night temperatures in Arizona and Egypt, but remarkably even thermometric conditions in California and Southern Europe.

Similar temperatures would be desirable in summer, but there are no really bracing conditions, readily accessible, on our side of the Atlantic, except on the north Pacific coast, where fogs and very high and damp winds prevail, and in the Canadian Rocky Mountains. For very young infants, the Middle Atlantic coast, the lowlands of interior New York and New England, the lake region, and the South California coast are sufficiently cool; after the first summer the New England coast, the Northern Alleghanies, the cooler Rocky Mountain points, and the most northerly stations on the Great Lakes are far preferable. Really cool summer days, averaging well below 70° (21° C.) in the afternoon, must be sought in the mountains of Central Europe and on the British Isles; the American continent has nothing in this line to offer, save what has been mentioned at the commencement of this paragraph.

At the risk of becoming wearisome, I must repeat that we have been very remiss in not paying more attention to the value of change of climate as a means of hardening young children; exposure to a moderately low, and therefore bracing, temperature is probably the best tonic at our disposal. It will be observed that I am saying nothing about the subarctic winter climate of the Adirondack Mountains and similar regions; I omit them because I am convinced that such extreme methods are certainly not required for prophylaxis against tuberculosis, though occasionally useful in the treatment of this disease in older children. In these very severe climates young children are kept indoors too much of the time by intense cold and heavy snowstorms, and, unless assiduous care be taken, or even in spite of it, the continuous battle with very low temperatures does young subjects more harm than good. At these early ages better results are undoubtedly to be obtained in such regions as North Carolina, Colorado, or New Mexico.

The second method of hardening children, usually but undeservedly regarded as the best, is the bath in its various forms. I regard bathing as somewhat inferior to climatic hardening in that its applicability is more limited and because its proper management requires far more skill and care. However, its usefulness cannot very well be disputed. We are passing the period when cold bathing was advocated for all ages, including infancy; nevertheless, I think that this form of hardening, like that of exposure to the weather, may be inaugurated at quite an early period, if a modicum of common sense and caution be employed.

Hardening by means of the daily bath may be achieved somewhat as follows: The temperature of the water, 100° F. (38° C.) during the first few months, may gradually be lowered to 95° (35° C.) by the sixth month, and 92° (33° C.) at the end of the first year. In the course of the second year the immersion at the last mentioned temperature may be followed by a brief sponging with cooler water, slowly going downward from 86° to 77° (30° to 25° C.). After the age of two years resort may be had to daily cool sponging, to be carried out in the following manner: The bathroom should have a temperature of 70° to 72° (21° to 22° C.), and the child should stand in water of about 92° (33° C.); it should then be sponged off rapidly with water, at the same temperature to begin with, lowering it to about 77° (25° C.) in the course of a minute or two, the sponging to be followed promptly by thorough drying with a rough and preferably warmed towel that envelopes the whole body. Within a year or so the temperature of the sponging water may

be reduced to 68° (20° C.) without harm, but lower temperatures are contraindicated, for they often seem to be injurious even to adults. Cold immersion should be resorted to with caution, as it presupposes considerable robustness; I would strongly advise against it before the sixth year, and then begin with moderately high temperatures, reserving those near 68° (20° C.) for puberty and beyond.

It is not easily explained, but may be verified by anybody on his own person, that cold sea or river bathing is more easily borne than cold tubbing. The probable reason is that the former is combined with a certain amount of muscular exercise, as in swimming. I must not fail to mention that the test of reaction, namely, a cutaneous hyperemia setting in after a minute or so, is as valuable a test of the wholesomeness of cool bathing in children as in adults. In infancy and the earlier years of childhood the reaction is not obtained as readily as later; its absence is an infallible sign that the bath, as given, is doing harm, and higher temperatures should be resorted to at once.

Sea bathing is an invaluable means of hardening children, but can hardly be resorted to before the fourth or fifth year, partly owing to the child's dread of the surf, partly on account of actual danger on coasts subject to strong breakers and currents. Another difficulty lies in the circumstance that the sea is rather cold at such resorts as have a bracing climate; regions like Long Island and New Jersey, where the temperature of the ocean is just right, are a little too enervating for robust children beyond the age of six or eight years. Fortunately, such relatively delicate children as call for care in the administration of sea baths also require a slightly warmer air temperature; the best way to surmount the difficulty mentioned is to take the child to a rather cool climate and shorten the bath, in extreme cases substituting indoor sea water baths for the more strenuous dips in the ocean.

Where the ocean temperature is about 60° (16° C.), as off Southern Maine, Middle California, the coasts of Germany, and the English Channel, the bath should last only a minute or two. A temperature of 65° (18° C.), as off Massachusetts, Southern California, and in the Bay of Biscay, permits an immersion of from three to five minutes; Long Island and New Jersey afford water temperatures near 70° (21° C.), and allow a ten-minute bath under these conditions; in the still warmer waters of the Mediterranean and Chesapeake Bay, where, however, the summer climate is far too warm even for delicate infants, the bath may last still longer. The common American custom of permitting children to stay in the water until cyanosis is developed is highly reprehensible, and one of the most objectionable methods of hardening known.

Still water baths require slightly higher temperatures, as is also true of fresh water; in the former case the massage of the breakers is absent, and we know that friction is almost a necessary adjunct to cold bathing. As to the latter, any one can try for himself that a salt bath feels warmer than one in pure water at the same temperature; the saline content of sea water and its stimulation of the skin is the determining factor.

Passing on to the subject of clothing, I can sum up quite briefly, for our knowledge of its hygiene is still imperfect. Some years ago wool next to the skin was deemed indispensable; at present a good many pediatricians regard it as altogether too pampering, preferring loosely woven cotton goods like Jaeger flannel and stockinet. It is well to note that some children, especially infants, have a skin so tender as to be greatly irritated by the jagged fibers of wool; the weaves of cotton just mentioned are almost as poor conductors of heat, and do not cause chafing. With the customary overheating of American houses rather light weights of clothing should be worn indoors, with heavy wraps for outdoor use in the cold months. The popular fad of semi-nudity for young children in summer calls for the sternest condemnation. It is hard to see why it has been applied to the very early years alone, the very age at which the body is less sensitive to high temperatures than later on, and is most likely to suffer from exposure to low temperatures. Holt[5] very properly says that permitting children to run about with bare arms and legs in midsummer is of questionable advantage even in our middle States, where although the day temperatures are rather high, considerable coolness may often occur in the early morning, and, especially at the seashore, toward evening also. My opinion is that this return to the costume of barbarism has no value except to facilitate the work of biting insects. Still more absurd is the idea of permitting children to run about barefoot; the only tangible result of this practice is to expose the child to the risks of traumatism in this age of nails and broken glass; furthermore, as the conventions of our civilization call for a return to shoes and stockings in later years, the final utility of learning to go barefoot is not obvious. Habits that must eventually be abandoned are hardly worth inculcating, the more so when their acquisition involves risk to health and a good deal of discomfort.

The respective tests of excess or insufficiency of clothing are simple—sensible perspiration in the former case, cold hands and feet in the latter. If a child suffers from coldness of the extremities, the only thing to do is to increase the amount of clothing or supply artificial heat; it is a great mistake to expect the child to harden itself by fighting off chilliness through metabolic stimulation alone. Much harm may be done in this way, for prolonged exposure to low temperatures invariably results in depression of the vital functions, and the child finally becomes what we call delicate. We must, of course, take care not to go to the opposite extreme and dress children too warmly or overheat their apartments, as enervation is quite certain to follow. Errors in both directions are committed continually nowadays, so that we are sometimes led to wonder if parents exercise any judgment at all in this important matter; it is at any rate the duty of the family physician to inform himself about this matter in the case of every child under his care. He will find the golden mean is kept in few families.

If this brief paper does not cover the entire field of personal and climatic hygiene in its relation to the prevention of tuberculosis in children it will, as I trust, at least have given an outline of a rational regimen. The more minute details will always have to be left to the individual attendant; general principles can, after all, inculcate little more than the maxim of *non nocere*.

BLOCKING STONES IN THE LOWER END OF THE URETER.*

By J. J. BUCHANAN, M.D.,

PITTSBURG, PA.

SURGEON TO MERCY AND COLUMBIA HOSPITALS; PROFESSOR OF SURGERY AND CLINICAL SURGERY, UNIVERSITY OF PITTSBURG.

It is my purpose to-day to present to your attention some practical considerations regarding the lodgment of stones in the ureter, with special reference to the diagnosis of this condition from attacks of acute appendicitis.

The ureter is not a tube with uniform diameter, but in the normal subject is found to have three points of narrowing; one at a position of one and one-half to two and one-half inches from the renal pelvis, at which point the diameter in the adult is usually about one-seventh of an inch. The second point of constriction is at the position where the ureter crosses the iliac artery at the brim of the pelvis; and at that location the diameter of the constriction is one-fourth of an inch. The third point of constriction is within an inch of the entrance of the ureter into the bladder, and at this position the constriction measures only about one-tenth of an inch. From these measurements, you will readily see that a stone of even very inconsiderable size may block the ureter and give thereby all the symptoms of nephritic colic.

The diameter of the lowest constriction being so small as one-tenth of an inch, it is at once evident that the gravity of the condition present is not to be measured by the size of the stone, but by the amount of impediment it offers to the passage of urine. Even a small stone may give rise to complete obstruction, whereas a larger stone may allow the urine to pass alongside of it. This apparent discrepancy in results is easily explained, when we consider that in almost all cases the pressure of urine behind the stone causes a dilatation of the ureter above, throughout part or all of its course to the kidney, and that this dilatation, which sometimes reaches the size of the index finger, may allow a stone not tightly impacted and of considerable size, to be so placed that some urine may constantly trickle past; whereas, a smaller stone may be so firmly impacted in the funnel-shaped end of the dilated portion that not a bit of urine may pass it. Small stones, therefore, may be just as serious threats to the patient as large ones.

Corresponding to the narrow places which I have mentioned, are the usual stopping places of stones, and we therefore find them just below the kidney, at the brim of the pelvis, or at the base of the bladder. The symptoms to which they give rise vary somewhat, according to the location of the stone. Stones blocking the ureter near the kidney or at the brim of the pelvis, give rise to symptoms which cannot be differentiated from stones in the kidney pelvis itself. These symptoms in brief, are lumbar pain of a colicky nature or of a dull character, radiating into the inguinal region, to the inside of the thighs, or into the testicle; retraction of the latter organ, blood in the urine, sometimes found only in microscopical amounts, at other times in considerable amounts, depending somewhat on the amount of roughening of the surface of the stone. By these symptoms alone, a diagnosis of stone in the upper ureter from stone in the kidney pelvis could not be made; but if the position of the stone is accessible to palpation, a tenderness may be found, and this is especially true if the stone is impacted at the brim of the pelvis. If the stone is impacted near the bladder, additional symptoms arise, connected with the act of micturition. There is a constant desire to urinate, the urine is passed frequently and in small amounts, and there may be even tenesmus of the bladder

The lower end of the ureter is accessible to indirect palpation through the vagina or the rectum, and in some cases, in addition to the tenderness displayed at this point, the stone itself may be felt with the examining finger. Pain also at the end of the penis is a characteristic of stone impacted in the lower end of the ureter, and the symptoms of this impaction are closely allied, therefore, to those of stone in the bladder. The important symptoms, therefore, of stone at the lower part of the ureter, are pain, bloody urine, tenderness, and frequency of urination. All of these symptoms, however, as I shall have occasion to prove to you by the cases which I shall relate, may be absent, except the pain and local tenderness.

When the impaction of the stone occurs suddenly, and is complete, the kidney may go on excreting urine, its pelvis may dilate until a hydronephrosis results, giving a tumor of greater or less extent. If it should be the right ureter that is involved, and the colicky pain should be of sudden access, and the tenderness be marked at the point where the right ureter passes over the pelvic brim, the diagnosis from an acute appendicitis becomes quickly an important one.

In these days, when we believe it to be so extremely important that every case of acute appendicitis should be operated on within the first twenty-four hours of its access, it can easily be seen that a condition which simulates it so closely may lead us into an operation under a mistake in diagnosis. We may have here a very violent attack of colicky pain in the right side, extending downward toward Poupart's ligament, with tenderness precisely at McBurney's point, and so severe as to indicate a case of great urgency. As I have said, this may occur without urinary symptoms, without blood in the urine, without frequency of urination, and with nothing to inform us for a certainty of the nature of the case. These cases are too urgent to permit of delay, till the patient shall have been transported to the *x*-ray machine, and they will not permit of delay until satisfactory pictures shall have been secured and repeated urinary examinations shall have shown the presence of minute quantities of blood, if it exist in the urine. They must be diagnosed by the clinical symptoms, and the decision must be arrived at by the probabilities presented to us by these symptoms. If these symptoms are solely those of violent pain and tenderness, then we must not risk the delay of operating on a probable acute case of appendicitis. The presence or absence of a leucocytosis would have a strong bearing on the diagnosis, but this sign is not of such an infallible nature that we would like to rest our diagnosis upon it alone. We are thrown back, then, upon the inevitable conclusion that, when a case of this nature arises and we are unable to say absolutely which condition is present, we must take the thing that is most likely, which is appendicitis, and the one which most urgently demands an operation, which is appendicitis, and the one which will not be harmed by an operation, which is appendicitis; and

*Paper read at meeting of Blair County (Pa.) Medical Society, November 17, 1908, and Columbiana County (Ohio) Medical Society.

we shall, therefore, in these doubtful cases, remove the appendix without delay.

I hope I may not be accused of advocating an operation which is unnecessary, or of laxness in making every effort to make a proper diagnosis before operation; but what I am now trying to state is, that there are cases in which a diagnosis cannot be made without delay, and that, rather than risk delay, I would prefer to do a simple appendectomy, even at the risk of having made a mistake; a mistake however which is never injurious to the patient.

That this error in diagnosis has been made by others than myself, is a well-known fact; for I have myself removed a stone from the right ureter of a patient whose appendix had been removed in a previous attack by a surgeon of eminence in New York, and a man who knew appendicitis thoroughly. Dr. George E. Brewer of New York has published a case in which he had removed the appendix in a case of stone in the ureter. Dr. Lilienthal, also of New York, has expressed his opinion that in some instances it is a practical impossibility to differentiate these conditions. The difficulty of making this diagnosis has been emphasized by cases recently reported by Dr. John H. Gibbon,[1] Dr. John F. Erdman,[2] Dr. Albert A. Berg,[3] and others. Two of the cases which I shall report were sent to the hospital for immediate operation for appendicitis, and one for appendectomy for recurrent attacks.

The prognosis of impaction of stone in the ureter is difficult to give. It may be stated, however, that a rapid destruction of the kidney function may arise from complete impaction and hydronephrosis; and on the other hand, many cases have been reported which have existed for terms of seven, fourteen, twenty-one, twenty-five, and even twenty-eight years. It behooves us to inquire—"What are the probabilities of the spontaneous expulsion of a stone from the ureter, when the symptoms clearly point to its presence in that tube?" I presume it is within the knowledge of every experienced and observant physician, to have had patients who suffered from the symptoms of renal colic, subsequently had bladder symptoms, and finally expelled a calculus, the symptoms having been so clearly consecutive that the passage of the stone could be traced from the kidney to the external world. These are stones, however, which have passed through the ureter without stoppage, and those to which I am now directing your attention are the ones that have met with an obstruction that has caused the stoppage of the urinary flow. When we have the symptoms of an obstructing ureteral calculus, the question arises: "Will this stone pass, or will it be detained sufficiently long to cause injury or destruction of the kidney?" This brings us at once to the question of the treatment of such cases. There is hardly a natural mineral water, whose proprietors do not claim for it the ability to wash stones from the kidney, ureter, and bladder, but I think that not one of us believes that any water, natural or artificial, has yet been discovered which has the property of dissolving a stone in the urinary tract. At the same time we all have known cases where patients with undoubtedly impacted stones have, by the drinking of large amounts of water, either at springs or at their homes, passed their stones, and remained thereafter well; and it would therefore seem to be the part of wisdom to advise all patients in whom the diagnosis is made, and whose condition is not too urgent to permit of delay, to drink large quantities of water either at their homes or at springs, so that the stone may be washed downward by the large amount of urine that is secreted.

In this connection, I might mention a patient, an attorney, who was sent to me about two years ago by Dr. C. Emmerling. This gentleman had been seen in an attack of colic by a prominent surgeon in an eastern city. He was urged to have his appendix removed, the attack being thought to be appendicitis. When I saw him, I was unable to find any evidences that this condition existed, and within a few weeks thereafter, he had another violent attack in which he passed large quantities of blood. An *x*-ray picture was then taken by Dr. Boggs, and the stone demonstrated in the lower end of the ureter. This patient went shortly afterwards to drink the waters at Cambridge, and the result was that he passed the stone and has since been well. We must, therefore, decide that every patient whose condition is not too urgent, should be allowed first to wash out his own stone by drinking either distilled water or the water from an appropriate spring. If this treatment should fail, we turn to the operative treatment, for the relief of the patient.

Up to this time I have said almost nothing about the diagnosis of this condition by the *x*-ray. I may say, however, that the diagnosis of the presence and position of a stone in the urinary tract, can be made with the greatest precision by the *x*-ray, and that the three cases which I will to-day report fully carried out the expectations that arose from an examination of the *x*-ray pictures made by Dr. R. H. Boggs. This is the greatest advance which has yet been made in this diagnosis, and while errors may be made by the examination of plates alone, the combination of knowledge from the plate and the clinical history will settle the diagnosis in most cases, although repeated sets of plates may be required.

Operative treatment for the removal of stones from the ureter has been undertaken in a very great variety of ways. Stones have been removed from the ureter by opening the kidney and passing forceps down the dilated ureter for the extraction of the stone. The kidney has been removed, to stop its secretion, and even the ureter has been removed with the kidney in a number of cases to do away entirely with the urinary secretion on that side and to remove the foreign body. The kidney has been opened and the stone pushed into the bladder by sounds passed through the dilated ureter. The ureter has been opened through a suprapubic cystotomy, an incision being made also through the base of the bladder, when the stone was impacted at the very end of the ureter. The ureter has been opened through the peritoneal cavity, by making an abdominal section. Stones have been removed from the vesical end of the ureter by exposing the ureteral orifice, through the cystoscope, dilating the orifice, and extracting the stone. The ureter has been opened for the extraction of a stone, by a vaginal incision, by rectal incision, and by a parasacral incision. Exposure of the ureter by opening the peritoneal cavity and cutting into the ureter through the peritoneum is generally considered to be a dangerous operation, because there is a very large probability of leakage of urine through the opening left by the extraction of the stone, and this extravasation of urine, if it passes into the peritoneal cavity, may result in fatal peritonitis.

We come now to what is considered the operation of choice, and this is the extraperitoneal ureterolithotomy. This operation is made by carrying the incision parallel with the fibers of the external oblique muscle, from a position somewhat internal to the anterior superior spinous process, extending it upward or downward, according to the location of the stone, carrying this incision through the muscular tissues, until the peritoneum is reached, lifting the peritoneum from the structures posteriorly, until the vessels and ureter are reached. The ureter follows the peritoneum, being more intimately attached to it than to the fascia behind, and when the stone is identified it is an easy matter to follow the ureter to the point of constriction and impaction of the stone. The stone is then coaxed upwards from its bed into the dilated ureter, if it is possible so to do. An incision into the ureter is then made and the stone is removed. A ureteral bougie is then passed downward into the bladder through this incision to make sure that the passage is now entirely free. Ureteral sutures of the finest silk or, preferably, of fine catgut are then introduced, a drainage tube is inserted, and the incision is closed. Even if a large amount of urine is extravasated, it is always external to the peritoneal cavity, and it escapes harmlessly and soon ceases to be discharged.

Case I.—The first patient whose case I report to you to-day, was a girl of sixteen, who applied to me on February 8, 1907, with a history of repeated attacks of cramps in the right side of the abdomen. The pain was so severe that morphine was required. Vomiting occurred during these attacks and feelings of discomfort between the attacks. Tenderness existed over the region of the appendix, and no history of blood in the urine could be elicited. The urine, however, contained albumin and casts. There was some doubt of the diagnosis and she was kept in the hospital five days before operation. Through a McBurney incision her appendix was removed. It was slightly adherent and decidedly thickened at the tip. The operation was short, without complications, and the patient returned to her home nine days later, feeling well and without discomfort. She shortly returned, however, complaining of pains of a similar nature, and it became at once evident that a new diagnosis had to be made. Blood in her urine was noted, and extremely frequent urination. She was sent to Dr. Boggs for *x*-ray examination and a positive diagnosis was made. She was urged at once to have the stone removed for it showed clearly on the plate. She and her parents, however, feared the operation very much, and owing to their delay it was not performed until August 29, 1907, a period of more than six months since the primary appendectomy. The incision just described was made and the stone removed from the very lower end of the ureter, not more than one inch from the bladder. A soft catheter was passed into the bladder through the ureter to make sure of its patency. Catgut sutures united the opening in the ureter and the patient was returned to bed. The stone was the size of a grain of coffee, with a conical tip, faceted at one end. After some leakage of urine from the wound, the wound healed kindly and the patient returned to her home. She was readmitted, however, a little over a month from the operation, with symptoms of advanced Bright's disease, almost complete suppression of urine, and dropsy, and died ten days later. Autopsy was refused.

Case II.—The second patient is a man, forty-one years of age, who had attacks of colic fourteen years ago, during which he passed calculi as large as the end of the finger. He had no attacks for seven and one-half years, until one year ago, when he had eight or ten attacks in four months which lasted about eight hours. This patient was sent by his physician to the Columbia Hospital as a case of appendicitis; but the history at once raised the question of an ureteral stone, and he was taken to Dr. Boggs, who made the diagnosis with a satisfactory *x*-ray plate. The extraperitoneal incision was made, and the stone, which was expected to be at the brim of the pelvis, could not be felt. The peritoneum was then incised and a finger passed down to the base of the bladder, and the stone located in that neighborhood. The peritoneum was then closed after the removal of a shrunken appendix, and the incision was extended downward to the base of the bladder and the stone removed, as in the previous case. The patient made an excellent recovery, after some leakage of urine, and left the hospital well.

Case III.—The third case was admitted to the Columbia Hospital on October 20, 1907, with a history of severe pain in the right side of the abdomen, with vomiting and marked tenderness over the region of the appendix. He was sent in as a case of acute appendicitis, and I saw him for the first time on the operating table. I removed his appendix through a McBurney incision. It was unusually long, measuring six and three-fourths inches, somewhat indurated, and covered with distended vessels. He made a normal recovery, as far as the wound was concerned, and went out, still having pain in the right lower quadrant of his abdomen. He was admitted again on November 15, not quite four weeks from the date of his operation, complaining of flatulence, vomiting, and pain of a colicky nature. No urinary symptoms. With the other patient in mind, a calculus was suspected. He was sent to Dr. Boggs, who made a plate giving a positive diagnosis. On November 23, a similar operation was performed and a mulberry calculus about six millimetres in diameter was removed from the very lower end of the ureter almost exactly at its entrance into the bladder. This patient also made a normal recovery, with some leakage of urine alongside the drain, and left the hospital on the seventeenth day, well and free from pain.

These three patients will serve to illustrate the points which I have endeavored to make in this paper:

1. The diagnosis between an acute attack of appendicitis and stone in the right ureter is sometimes impossible.

2. If the acuteness of the attack is such as to require an immediate operation, in case the condition should turn out to be an appendicitis, the immediate removal of the appendix is indicated, which being under these circumstances a harmless operation, removes the immediate danger.

3. The diagnosis by the *x*-ray, in competent hands, is accurate and satisfactory, and every doubtful case should be submitted to this test.

4. Every part of the ureter can be exposed by the extraperitoneal operation, which in a patient in an ordinary condition, seems to be practically free from danger.

ROENTGEN DIAGNOSIS OF CALCULI.*

By RUSSELL H. BOGGS, M.D.,

PITTSBURG, PA.

The first essential in radiography of renal calculus is proper preparation of the patient. The intestines should be as empty as possible. There are two reasons for this:

(1) Fecal masses sometimes cause definite shadows, but usually do not present any difficulty in the way of diagnosis. I have seen cases in which there were shadows resembling calculi, which disappeared after a cathartic had been given. Drugs, such as bismuth, Blaud's pills, or any dense substance, will cast shadows on the plate, and would be at least confusing.

(2) By having the intestines empty there is not only less density, but the colon, as a rule, is filled with gas and greater differentiation of the abdominal contents is obtained.

All buttons and pins being removed, the patient is placed on the table, either in a dorsal or prone position, depending upon whether the tube is above or below the table. It is advisable to have all clothing removed between patient and plate, as occasionally the folds will show. The patient can be covered with a sheet, and this will not interfere in any way with the examination.

For the first exposure, I use two 14 x 17 plates, one on the top of the other. This will take in both kidneys, ureters, and bladder. The reason for using two plates is that occasionally imperfections occur in the emulsion, which may simulate a calculus, but will never occur on two plates in the same place. After these two plates are developed and studied, if there are any faint shadows, other plates are made using a small diaphragm and compression method; this takes smaller areas, but the plates are clearer and have greater differentiation and are extremely valuable in difficult cases.

For the first exposure, which includes both kidneys, ureters, and bladder, the tube is in the median line and focused directly over the umbilicus, at a distance of twenty-two inches from the plate. When using a small diaphragm, the tube, of course, is focused over the center of the area examined. When examining for calculus in the lower portion of the ureter, it is important to have not only one radiograph with the tube focused over the pubis in order to determine, as nearly as possible, the position of the calculus, but to make a radiogram with the tube placed over the umbilicus, focused so the rays will show the shadow of the stone in the soft parts of the pelvis, and not on the sacrum, as will be done in certain portions of the ureter if the tube is placed directly over the calculus. This is very important if the calculus is small and is composed of uric acid or its salts, as such stones do not show plainly. In several instances I have been unable to locate a calculus in this position until the radiogram was made at this angle.

The time of exposure has been so shortened that with the latest apparatus it is necessary to give only from five to ten minutes. Whenever possible the exposure should be made while the patient is holding his breath, in order that there be no movement to blur the shadows. It has been stated that the kidneys move in some cases as much as one and one-half inches during respiration.

*Read at a meeting of the Blair County (Pa.) Medical Society, November 17, 1908.

Again, in regard to the quality of the tube. A higher penetrating tube should never be used than is absolutely necessary. It is claimed by certain authorities that, with a very high penetrating tube, small calculi of low atomic weight, such as uric acid, may be overlooked.

A plate should reach a certain standard and show the articulations and spinous and transverse processes of the lumbar vertebræ, crest of the ilium, last two ribs, psoas muscles, and bony details of the pelvis, before any attempt is made to give a positive or negative diagnosis by the *x*-ray.

In 1898, Dr. Charles Lester Leonard pointed out that if a plate reaches the above standard, both positive and negative diagnoses could be made with fair degree of accuracy. He based his belief on the axiom, "that where shadows of tissue less dense than the least dense calculus are shown, no calculus should escape detection." Only in negatives that fulfil these requirements can an accurate negative or exclusive diagnosis be made, and time has shown that such negatives, given sufficient experience in reading them, prove this proposition to be correct.

The intensity of the shadow varies with the size and composition of the calculus, uric acid being the least opaque. Calculi are mostly composed of uric acid and its salts, calcium oxalate, calcic and ammonium phosphate. Occasionally other substances such as carbonates and cystin are found.

A Roentgen diagnosis means more than making beautiful plates. Interpretation of the plates requires as much care as in making the examination. A shadow on a plate means nothing unless the patient's symptoms coincide with the findings. All of the clinical symptoms should be taken into consideration, and a diagnosis should be made in conjunction with the other recognized methods. A hasty diagnosis, made oftentimes when the patient has been radiographed for fracture of the hip joint, etc., has brought the Roentgen method into disrepute.

I am under obligations to Dr. J. J. Buchanan for the valuable instruction he has given me in symptomatology during the past five or six years, and also for assisting in determining what caused some of the abnormal shadows seen on plates, in the region of the kidneys, ureters, and bladder.

The following may cause shadows, but there is usually a difference in the shape and density of the shadows produced by them from those cast by calculi: (1) Foreign substance in the intestines; (2) calcified glands—tuberculous, sarcomatous, carcinomatous; (3) phleboliths or calcareous deposits in atheromatous vessels; (4) sesamoid bones; (5) fibroid of ureter; (7) warts or moles on the skin next to the plate.

Calculi in the ureter are in the line of the ureter, and their shape is usually round or more or less oval. The ureter crosses the transverse processes of the vertebra and enters the pelvis a little to the inner side of the sacroiliac synchrodrosis. So if a shadow is seen on a radiogram, if it is cast by a stone in the ureter it must be in this line unless the tube was so placed as to distort the shadow or unless the ureter itself is in an abnormal position. In all doubtful cases a careful and thorough study of the symptomatology and history in connection with the plate will show whether a diagnosis of stone is justified.

[illegible] Ewing Building.

MEDICAL AND SANITARY INSPECTION OF SCHOOLS.*

By RICHARD COLE NEWTON, M.D.,

MONTCLAIR, N. J.

Medical inspection of German schools was begun in Dresden in 1867, when three physicians, formerly teachers of physical training, were appointed to examine children suffering from a contagious disease of the eyes. Not until twenty-two years later, however, was a genuine system of medical inspection of schools inaugurated in that country. In 1898, this system was made general throughout the empire, and after its introduction an entirely new phase of the work of the school inspectors was developed.

The chief characteristic of this method is the great importance which attaches to the hygiene of the scholar without in any way disregarding the hygiene of the school building. The medical inspection in the German schools which had begun to relax in its efficiency, has since the introduction of the new plan gained rapidly. Wiesbaden was the first German city to make a test examination of all pupils, whereby an unusually high percentage of defects was revealed, of which the pupil, the teacher, and the parents were wholly ignorant. The Wiesbaden school authorities soon realized that a complete physical examination of all the children entering the schools was of the utmost importance, and the following plan was adopted:

Systematic examinations are made of the heart, lungs, throat, spine, skin, and the higher sense organs (and in the case of boys there is an examination for hernia also). The findings are entered on a report blank, which accompanies the child from grade to grade in his school life. Twice a year the teacher records the weight and height of individual pupils. Whenever it is deemed necessary, the school physician takes chest measurements. The records of children who seem to require the regular care of a physician are marked accordingly, and such children show themselves at stated intervals to the school physician. A careful re-examination of all pupils must be made in their third, fifth, and eighth school years. It is also the duty of the school physician to give advice to the teachers in regard to the children, and when defects requiring special medical attention are discovered, the parents are notified. It is not expected that the school physicians will give medical treatment to the scholars.

In the United States, Boston seems to be entitled to the credit of establishing the first regular system of medical inspection of schools, which was done in 1894. Although two years before this the sanitary inspector of New York City had appointed a Medical Inspector of Schools, who was probably the first medical officer of the public schools appointed in this country. In 1894 50 physicians were selected by the Board of Health to inspect the public schools of Boston. In 1895 nine such inspectors were appointed in Chicago. In 1897 the Board of Health of New York City appointed one hundred and thirty-four medical inspectors for the public schools, with a chief at a salary of $2,500 per annum. In 1898 the Bureau of Health in Philadelphia passed a resolution directing that each one of the fifteen assistant medical inspectors shall visit one public school in his district each day, inspecting it according to the methods employed in Boston, New York, and Chicago. Since 1894 medical inspection of schools has been largely adopted throughout the United States, and in some States has developed from mere inspection for detecting contagious diseases to systems calling for the most thorough physical examinations. Only four general state laws providing for or allowing medical inspections of schools have been passed. They are as follows: In Connecticut, in 1899, the legislature passed a law providing for the testing of eyesight in all the public schools of the State. New Jersey has a law, which went into effect in 1903, authorizing boards of education to employ physicians, or medical inspectors of schools, and defining their duties. Vermont followed in 1904 with a law requiring an annual examination of the eyes, ears, and throats of school children. In 1906 Massachusetts passed a law which is comprehensive in its provisions and mandatory throughout the State.[1] It requires every town and city to establish and maintain a system of medical inspection by competent physicians for the detection of contagious diseases in the schools. Examinations must also be made annually, by the inspectors, of all the scholars for non-contagious physical defects, and their eyesight and hearing must be tested every year by the teachers.

Without authoritative and specific enactment, the State Boards of Health of New York, Utah, and California, have caused examinations of the eyesight and hearing of school children to be made. There is, so far as can be ascertained, some form of medical inspection of schools in vogue at present in seventy cities in the United States, outside of Massachusetts.[2]

From the data given we can see that the United States are behind Germany and, for that matter, a number of foreign countries in this important movement, but we also see from the rapidity with which the movement has spread in this country and the great and increasing interest which it has excited, that its benefits have been widely recognized, and that with intelligent supervision and careful study a complete and efficient system, not only of medical and sanitary inspection of schools, but of physical education of all school children both in public and private schools, will in a few more years be inaugurated in America. A number of questions must be settled before this great advance can become general.

We see very plainly that medical inspection of schools is as yet in its infancy in the United States. I am aware of only one town in America where this inspection is carried out with considerable thoroughness, and that is Brookline, Mass. The ordinary method of school inspection in the United States consists chiefly in the visits of a physician to a school twice a week (or when summoned) to examine certain scholars already selected for inspection by a teacher in order to ascertain whether they may have a contagious disease and may thereby be dangerous to their fellows. This is a most excellent measure, so far as the prevention of epidemics is concerned, yet it can have little influence on the physical education of the child or the sanitation of the school buildings. The examinations for physical defects of one sort or another, which are carried

*A part of the report of the committee on this subject, made to the New Jersey State Sanitary Association at Lakewood, December 5, 1908.

[1] This is the only mandatory State law so far enacted.

[2] Most of the data heretofore quoted can be found in the recent work on School Hygiene by Drs. Gulick and Ayres.

out annually as a rule in New York and other cities, reveal an astonishingly large percentage of such defects, and these results are in accord with the reports of similar examinations which have been made abroad. Without stopping to quote figures, it would seem that fully two-thirds of all children in the primary grades of the public schools are suffering from physical defects more or less pronounced.

In Germany, Cohn found that myopia increased from 1.4 per cent. in the free village schools to 19.7 per cent. in two realschulen and 26.2 per cent. in two gymnasia, reaching the astonishing figure of 59.5 per cent. in the university. As Risley points out, this increase in myopia has gone steadily on in Germany in spite of the improved hygienic surroundings in the schools. That this defect has any such alarming increase in the schools of the United States is not likely. However, this question, as well as many others, requires careful study, and will no doubt be vigorously pursued by the school inspectors of the future.

The teeth of school children would seem also to have received far more careful attention in Germany than in this country. A dental clinic has been established in Strasburg where the cost of taking care of the teeth of the public school children has been found to be 25 cents a year for each child, with a resulting great diminution in absences, not only from toothache, but from other diseases, including infections. In Chicopee, Mass., out of five hundred children, who were tested as to their physical condition, 499 of them had defective teeth, and the 500th child, whose teeth were perfect, had spinal trouble, giving a hundred percentum of defectives in the 500 examined. A series of elaborate examinations of the eyes, ears, teeth, weight, height, heart, and lungs, and in fact entire physique of the children in the public schools of Brookline, Mass., were made last year, and the interesting results were published and furnished food for serious study.

The question is constantly staring us in the face, whether great and permanent injury to our children's health is not being done in the public schools. Certainly all the experimental work that has so far been carried out goes to prove that our schools are needlessly expensive, and in many cases do irreparable damage to the health of our children. Those who have attended school for half time, or who have not begun school life until eight or nine years of age, have so frequently surpassed those beginning much earlier and spending more hours in the schoolroom, that we may well pause and inquire whether the seeds of most of the nervous breakdowns in our feeble young Americans are not sown in the early years of school life; and whether our methods of public instruction for the young are not unduly extravagant and wasteful, not alone because we try to teach them the "forty frills," as well as the "three R's," but because we insist on their beginning school at least two years too early, when they should be playing in the fields,—and by our tedious school hours, ill-ventilated rooms, superheated and steam-dried air, we cause much of the bronchitis and pneumonia, not to mention the contagious diseases, which we pay the medical inspectors to detect.

Some better systems of heating school rooms must replace the steam-dried air now in use, which is a chief cause of bronchial sickness and colds, not to mention the lassitude, headaches, and lack of the power of concentration noted among our school children through so much of the cold weather. A so-called "hospital system" of heating has been introduced in some buildings, by which a large quantity of fresh air is sucked into an air chamber by a large fan, through muslin screens, passing over a large steam coil which heats it, and then over a tank in which steam is generated, which introduces the necessary moisture into the current of air to replace that which has been dried out by the steam.

Naturally in connection with heating, we must consider also ventilation, which is generally speaking the *bête noir* of all public buildings. At the last meeting of the American School Hygiene Association, the experts present declared that no really satisfactory system of ventilation has as yet been devised for public schools, and that no matter how elaborate or expensive a ventilating plant may have been installed in a school building, pure fresh air for all the scholars in all the rooms is only obtainable in many instances by opening the windows —a maneuver which the inventors of ventilating systems especially deprecate.

There is no question of the advantage which has invariably followed the appointment of the school nurse. There should be one of these important functionaries, if possible, in every school building. At least there should be, as Dr. Cronin of the New York Board of Health recommends, one nurse and one medical inspector for every 2,000 school children. There is absolutely no difference of opinion as to the school nurse's usefulness in every place where she has been installed. She instructs and helps the ignorant and wins their confidence and good will to an extraordinary degree. In New York City she receives $75 per month during the school year, and is said to save the city much more than the cost of her salary every year by the prevention of the spread of contagion. She visits and instructs the families of pupils who are sent home from school because of sickness. She ascertains whether the pupil's disability arises from anything in his home, and whether he may get such care at home as to render him fit to attend school again. He indeed may be suffering from trachoma or some other contagion which he has contracted from the members of his own family. She also prevents an almost incalculable loss of school time by cleaning the pediculous heads, administering the necessary baths, etc., to the pupils without sending them home, where, very likely, these useful functions will not be performed from want of facility, or knowledge, or lack of the disposition to do the proper thing. The school nurse also soon becomes quite an expert in the detection of infectious diseases, as well as malingering among the scholars, and she should be a most efficient aid to the sanitary officer in regulating the heating, ventilating, etc., of the buildings.

A most important question has arisen in various localities in regard to the control of the medical inspection. In some places this is vested in the board of health, and in others in the board of education, consequently at times some friction has arisen by reason of uncertainty in regard to the status and the duties of the inspectors. The matter can be easily arranged if it is clearly understood that the inspection for the detection of contagious diseases is a part of the duty of the health board. Whereas the detection and correction of non-contagious diseases and defects is, strictly speaking, a function of the physical education of children, and, as such,

should come under the supervision of the board of education. Of course the two boards should work in harmony, in fact, in my opinion, they will be eventually consolidated. The day of the elective school board is fortunately passing away. Prosperous merchants and aspiring politicians have got themselves elected to school boards by unsuspecting citizens for many years. They have rivaled each other in their complacency and in the easy view which they have taken of their duties.

If there is one sign of the times more pronounced than another, it is that the public school, if it is to survive, must prove to the people that the education it provides is efficient and solid, and that the health of the scholar shall be in every conceivable way protected and enhanced during his school life. These are the days of efficiency and of simple and direct methods of activity. Hence, the large elective school board is passing away, the smaller and more efficient appointive board is taking its place.

Perhaps the greatest need in the educational world at present is for medical men, sanitarians, and architects on the boards of education, men who, if not themselves experts, are competent to select experts and to judge of their work. The plan now in vogue in Boston of hiring the best available architect, engineer, etc., in the city to supervise and construct all the school buildings, should be adopted in every city and should be extended to the employment of at least one thoroughly competent chief medical and sanitary inspector. This man should be responsible to the board of education, by whom he should be hired and discharged, and should have complete control of the sanitation and hygiene of the school buildings and of all the scholars. In the matter of ventilation, heating, drainage, playground space, control of athletic sports, hiring and discharge of physical and gymnasium directors and teachers, he should be subordinate only to the superintendent of schools and the board of education. In other words, this matter of physical education and sanitation of schools and scholars can scarcely be on a satisfactory and efficient basis in any community until it is placed under a responsible and competent head.

The present so-called medical inspection of schools is only a detail of the scheme just outlined and might be left in the hands of the board of health, or taken over by the board of education as circumstances and economy should dictate in each particular case. Every town having 2,000 or more school children should employ a chief medical officer of instruction, at a yearly salary of not less than $3,500, who should give his entire time to the schools during the school year, and should supervise the playgrounds, and the out-of-door physical instruction during the summer. He should be allowed to employ as many nurses as might be needed at a compensation of $75 a month, and as many physical instructors, both male and female, as might be required. He should have charge of all the records and statistics bearing upon the physical condition of the children and of the sanitation of the buildings. He should cause to be kept a card catalogue containing the physical history of each scholar, so that he could make a report on any one child, on any one thousand children, whenever he might be called upon to do so. He should also have charge of the instruction of the teachers in hygiene and physical education, should deliver lectures himself, and be empowered to hire what help he might need in this department.

As Dr. Greenwood has ably demonstrated, in his admirable reports of school inspection in Blackburn, England, the teachers are "our first line of defense" against contagious disease, against overwork, impure air, and all the deterrent influences which are injuring our children in school. That American teachers are as yet for the most part in abyssmal darkness as regards these important matters, is a lamentable, but not irremediable state of affairs.

Dr. Greenwood, with comparatively little trouble, having the support and cooperation of the school authorities, has succeeded in a short time in enlisting the interest and sympathy of the teachers in the Blackburn Schools in the health movement, and a number of them have prepared themselves and passed creditably examinations in hygiene and sanitation, thereby not alone obtaining more responsible positions and earning better salaries, but greatly improving and broadening their views of a teacher's duties and responsibilities, and strongly enhancing the pleasure and interest of their work.

Watching the human plant unfold and develop in a favorable environment, and careful study of the means of improving and enlarging that environment until the plant shall more and more nearly approach the perfection which the Great Author of our being intended us all to reach, is the great privilege of the teacher of children. Viewed from this standpoint, the teacher's calling is the noblest in the world.

Shall we not as parents and good citizens do our part to render the teacher's work effective and satisfactory?

PURPURA HÆMORRHAGICA; IS IT CAUSED BY THE COLON BACILLUS?*

By STEPHEN J. MAHER, M.D.,

NEW HAVEN, CONN.

"Doctor, what are these two red sores?" asked a laughing, plump, twenty-five-year-old school teacher in my office on the evening of December 4. She pointed to two small bloody blebs, one on the ring finger of her left hand, and the other on the cutaneous margin of her under lip. Before I answered her question I found that there was another bleb on the middle of her tongue, and that there were a score of flat purple or red spots on her arms and chest.

The next day she had a sharp nosebleed. The next day she vomited blood. That night she had blanching hemorrhages from nose and stomach and bowels and bladder. The fourth day she improved considerably. The fifth day she had a recurrence of the terrible hemorrhages from all the mucous surfaces. The sixth day she had more hemorrhages and died. The treatment consisted of the calcium salts, lactic acid, quinine, adrenalin, and cardiac stimulants.

The patient came of an unusually healthy family. She herself had had no sickness for years except two attacks, a year apart, of a skin disease that I had diagnosed as ivy poisoning. During the past autumn she had had some bother with constipation and had frequently felt unaccountably sleepy on coming home from school. She was careful about her diet but ate plentifully and was especially fond

*Read before the New Haven Medical Association, January 6, 1909.

of fruit. She ate no shell fish and very few sweets.

For a number of years she had been annoyed with what she called "gas spells." About once a week and usually without warning, she would be conscious of great distress in the upper abdomen and would be obliged to strain violently in efforts to eruct gas. These attacks generally ended in vomiting.

On the evening of Friday, November 27, she felt chilly and took a few grains of quinine and went to bed. During the night she had a very severe "gas spell." The next day she was tired and sore and remained in bed most of the day. The next day she was entirely well and in the afternoon went to the theater. She taught school the following week and seemed as well as usual until the evening of Thursday, December 3. Then she had another chill and again took four grains of quinine and went to bed. She complained a great deal of the intense cold that she felt. Again during the night she had to get out of bed because of stomach distress. She vomited so long and with such painful labor that her family, accustomed though they were to her "gas spells," became alarmed and were about to send for a physician, but suddenly the attack was over and she went back to bed. She slept until noon the next day, and when she arose her sister noticed the red blisters on her finger and lip. The patient laughed at them and said they were probably due to the quinine. She taught school in the afternoon and called at my office in the evening.

All through the few days of her fatal illness I was interested in the fact that various cervical glands would swell to the size of a pea, become very painful, and then after a few hours return to the normal state in size and sensation. When the blebs on the lip and tongue fell off, as they did toward the end, they left deep, circular pits. Her temperature never went over 100 degrees, and was usually 99 degrees. She retained consciousness almost to the last.

Much as I wanted to draw off some of her blood, I didn't feel that under the circumstances such a procedure would be justified. However, I supplied the nurse with a wide-mouthed one ounce sterile bottle, and instructed her to secure for me the cleanest possible specimen of blood.

On the afternoon of the fifth day the patient had in quick succession two hemorrhages of nearly a quart each from the bladder. The nurse filled my bottle from the second hemorrhage. Smears of this blood, stained with Wright, Gram and Gabbett, showed that many of the leucocytes contained clumps of a small coccobacillus non-acid-fast and usually gram negative. There were a few extracellular clumps of this bacillus in the smears, but they were usually near to burst or torn white cells. There were no free individual bacilli in the blood.

Cultures from the blood on various media gave pure growths of this same organism. It curdled and reddened litmus milk, caused effervescence in sugar bouillon, produced gas and yellowed neutral red in the fermentation tubes, and, in a word, responded to the ordinary tests for the *Bacillus coli communis*. Smears from glycerin agar and from hard serum still showed some individuals that were distinctly gram positive, and some of the negative bacilli contained gram positive polar beads.

On December 10, I injected intraperitoneally the growths on Loeffler's serum and sugar bouillon into a guinea-pig, and that from sugar bouillon alone into a white rat. The rat was very sick for 36 hours, but recovered. The guinea-pig died in 12 hours. Autopsy of the pig showed tremendous inflammation of all the serous surfaces, a large black spleen, a distention of all the blood-vessels in the body, and beautiful purpuric patches throughout the wall of the large intestine. These are still well shown in Specimen No. 1, preserved since in Pick-Kaiserling solution.

Plants from the heart's blood, from the peritoneal exudate, and from the spleen, gave prompt growths of the organism injected.

To learn whether this spectacular find was accidental or not, I injected on December 16 three other guinea-pigs. Pig A, with the organism recovered from the heart's blood of the guinea-pig just described, B, with the cultures of the organism isolated the day before from the patient's blood, and C, with cultures of the organism first isolated from the patient's blood, and which had been in the incubator for eight days. All three guinea-pigs died within 12 hours, and all but C, showed the same purpuric lesions in the bowel wall and the same evidences of intense serous inflammation. Pig C had very little peritoneal exudate, but a pronounced pleuritis and pericarditis. The heart's blood of all three pigs gave identical cultures of the organism isolated originally from the blood of the patient.

Later injections of this organism into pigs of the third and fourth series gave the same pictures of purpuric spots in the wall of the intestines.

On December 21, I gave to the white rat that had recovered from the first injection, another intraperitoneal injection, this time of the cultures of the organism recovered from the purpuric pig in the second series. Again the rat was very sick for a couple of days, then slowly recovered its agility, and after a week seemed quite well, but on the eighth day died. Autopsy showed only some red and blackish not well-defined areas in the bowel walls. There was no sign of serous inflammation, and there were no distinctly purple spots. The blood contained no bacterial forms and gave no growths on culture; but the spleen, dropped into a tube of sugar bouillon, gave a pure culture of an organism apparently identical with the one injected. It curdled and reddened milk more slowly than did the original, and more slowly than the colon bacillus ordinarily does.

A guinea-pig injected January 2 with cultures of the bacillus recovered from the spleen of the rat, was dead and stiff within 19 hours. Autopsy revealed the usual pictures of serous inflammation, but there were no satisfactory purpuric spots in the bowel wall; but there were cheesy flakes in the exudate and many small soft cheesy spots in the liver. The general picture suggested that found in the first days of that very fatal and infectious disease of guinea-pigs called pseudotuberculosis. A repetition of this experiment and an injection of another pig with the organism recovered from the one last described, showed that the organism after its passage through the rat had lost none of its power to produce purpuric patches. The specimens in the dish show purpuric patches in bowel wall and stomach wall of the two pigs injected with the bacillus that had been through the rat. The loss of power to produce the purpuric lesions was only temporary.

Smears made January 1 from the original blood of the patient, which, by the way, had been kept at room temperature ever since it was brought to the

laboratory on December 8, and in which there was no clotting, showed short chains of rods, half gram positive and half gram negative. There were no intact white cells, but the red cells were as round and fresh in appearance as if they had just come from the living vein.

Cultures from this blood made January 1, gave in 24 hours apparently pure cultures of the injected organisms, except that on all the media there was a larger proportion of the gram positive individuals than appeared in the cultures made 24 days before.

A guinea-pig injected January 5, with cultures made January 1 from this old blood died within 12 hours, and showed the same purpuric spots in stomach wall and bowel wall, and the same black spleen and congested lungs as were seen in the first guinea-pig injected from cultures from that same blood four weeks before.

In Osler's "Practice," the author does not attempt to discuss the cause of purpura hæmorrhagica. He says merely of purpura in general that, "In the present state of our knowledge, a satisfactory classification cannot be made."

In Allbutt's "System of Medicine," Stephen Mackenzie dismisses the suggestion that purpura may have a bacterial origin, in this wise: "In recent years great attention has been devoted to the search for microorganisms in the blood-vessels, and in the tissues. Various bacteria have been found by different observers in some cases, but in other cases the same observers have failed to discover them. The presence of microorganisms in the blood-vessels, even in large numbers, as in diphtheria or anthrax, does not necessarily give rise to hemorrhage; moreover, apart from the negative results of the search for bacteria, the circumstances in some cases in which it occurs make it unlikely that the causes are of this kind."

Thompson's "Practice of Medicine" says that purpura hæmorrhagic "is of unknown origin. Some acute cases suggest its infectious nature. It occurs in children and also in young adults, especially females debilitated with disease."

So far as this case may provide a basis for a satisfactory answer to the question asked in the title of my paper, it is important to remember the following points:

1. The recently extravasated blood of this case of malignant purpura hæmorrhagica contained clumped in its leucocytes bacilli having the cultural and other characters usually ascribed to the colon bacillus.

2. The bacilli isolated either from the fresh or from the old blood had the power on intraperitoneal injected into guinea-pigs, not only to kill the animals in a few hours, but to produce on the wall of the animal's intestines and stomach purpuric patches identical in appearance with those that characterized the disease in the human body.

3. This power to produce purpuric patches on the walls of the intestines of the injected animal was striking and constant even after the bacillus had passed through four series of guinea-pigs.

4. This power was diminished in the cultures that had been kept for eight days or more in the incubator, although the keeping of the cultures fourteen days in the incubator did not lessen the pathogenicity of the bacillus.

5. The white rat, though more resistant to the first cultures of this bacillus, succumbed in exactly the same way as the guinea-pig when injected with the bacillus that had been through four guinea-pigs.

6. The colon bacillus, although usually fatal to injected guinea-pigs, does not kill so quickly and does not cause the appearance of purpuric patches on the intestinal and stomach walls of the injected animals.

I wish to thank Dr. Bartlett and Dr. Blumer, who was the consultant in the case, for their interest and help.

212 Orange Street.

Our Actual Knowledge of Radium.—Crescenzo Esedra limits himself to the therapeutic affects of radium. He states that the radium rays render the soil on which bacteria grow unfavorable to their growth, as well as to their action. Canine rabies, both in the test-tube and in the individual, is destroyed by the action of radium. Malignant tumors have not been cured by the use of radium, but in cases of tumors that do not grow too rapidly radium is a valuable adjunct to other methods of treatment, a useful means of relieving pain and hemorrhage, and when the tumor causes stenosis it may be used to obtain a permanent dilatation. Encouraging results have been obtained in several other diseased conditions. It produces perfect cosmetic results in cutaneous cancer; recurrence is rare, and cure is easy. All the benign tumors of the skin and muscles are benefited by radium. Angiomata, especially of young children, are benefited, the treatment being easy and painless. It may be used in any part of the body, and leaves no trace of its action. It cures lupus, and benefits all the chronic skin diseases. It is valuable in neuralgia and painful joint conditions. In anatomopathology it is found to produce an action of destruction on lymphoid tissues, obliterates the blood-vessels and muscular fibers undergo granular degenerations, as do the hepatic cells.—*Annali di Elettricita Medica e Terapia Fisica.*

Fleas and Plague in the Old Testament.—Sir Havelock Charles contributed recently to a contemporary an ingenious speculation concerning an incident recorded in the Book of Samuel which has given rise to much discussion on the part of commentators. It will be remembered that when in the warfare between the Israelites and the Philistines the ark of God fell into the hands of the latter it was followed in its travels by "a very great destruction," the men of the cities of the Philistines where the ark rested being smitten with "emerods in their secret parts." Eventually the ark was restored to Israel, only to cause a worse destruction, fifty thousand and three score and ten among those who pried into it being smitten. It is recorded also that mice marred the land of the Philistines at that period, and they must have been supposed by the Philistines to have some relation to the prevailing epidemic, since images, not only of emerods, but of mice, were made to allay the anger of God. Sir Havelock Charles suggests that in the story we have an account of an epidemic of plague. The ark, he says, during its stay in the temple of Dagon, infested, like all Eastern temples, with rats, became infected by plague-laden fleas, to which its covering of badger skins gave safe harbor. During its subsequent travels, even till it came to the prying Israelites of Beth-shemesh, it distributed plague. When the ark became safe from further inquisitive meddling, its power of propagating disease disappeared.—*Medical Press.*

Medullary Anesthesia.—Giuliano Gerundo has had very favorable experiences with the use of stovaine by lumbar puncture in surgical operations. It produces a mixed sensory and motor paralysis without bad effects of any kind. Its upper limit is the lower border of the ribs, and the anesthesia is perfect in the external genitals, perineum, and legs. With a dose of four centigrams we obtain a complete paralysis of the legs lasting a variable time. The action is superior to that of cocaine in its rapid diffusibility and lack of poisonous effects. It has no toxic action on the heart, being a heart stimulant. It regulates the pulse and slows it. The author has used this anesthetic in 125 cases, with only four failures. The confidence of the patient in the drug is of great assistance in getting the desired effect. Anesthesia began in two to five minutes after the injection. Five centigrams produce an action for forty to fifty minutes, while six or seven centigrams give anesthesia lasting one hour, and ten centigrams two hours. The author considers this method of practical value, superior to any other, and of great value in military surgery on account of its rapid action. Made with rigid asepsis, there is no danger from the injections. When acidulated with lactic acid the effect of the solution is better.—*Giornale di Medicina Militare.*

MEDICAL RECORD.

ALIMENTARY FEVER.

FEVER and infection are terms that are nowadays thought of almost at the same time. The moment a rise of temperature occurs in a patient the observer seeks for some focus of microparasitic activity, since this it is which exerts a greater influence upon the temperature than any other phenomenon of disease. Our predecessors, however, who lived in the days before the general acceptance of the germ theory of disease, did not think of fever in this connection only, but considered that various other circumstances could produce a similar effect upon the temperature of the body. Nutrition was the most important process, the derangements of which could be held responsible for the phenomena of fever, and in the *Deutsche medizinische Wochenschrift* for February 4, 1909, a very modern representative of the science of nutrition, Finkelstein, argues that the older physicians were not quite so wrong in their views as we have been wont to think. To him the fever accompanying the many states of poor nutrition in infants is not always to be traced to infection from the gastrointestinal canal or even to the absorption of toxins produced in that tract by abnormal changes in the foodstuffs introduced. The best proof of the "alimentary" character of such fever may be had in the marked influence exercised upon its course by withholding of all food from such patients for one or more days. The fall in the fever is so rapid that the close connection of some metabolic processes with the rise of temperature can hardly be doubted; indeed, it requires but little carelessness or undue haste in the resumption of food to bring back the whole symptom-complex characterized by fever, prostration, vomiting, etc., etc.

Of course, infants present the best examples of such alimentary fever simply because their reactions to disturbances of metabolism are much more acute than those of adults. Finkelstein claims further that these reactions are almost specific, the carbohydrates of the infant's food being the most frequent causes of these disturbances of health characterized by fever. That Biedert's views of the all importance of proteids in the production of abnormal states in childhood have been disproved seems almost sure. Finkelstein, for instance, mentions the very striking experiment in which he gave casein mixtures to a child suffering from a metabolic disturbance characterized by fever. Such food had the same effect as the more usual administration of water would have had; the temperature of the children always fell, thus apparently proving that the caseins were as easily borne as water. The relation of sugars to the fever could be experimentally shown in a great number of instances, mere injection of sugar solutions per rectum leading to renewal of the toxic conditions in infants. Indeed, so rapid was such action that Finkelstein sees the effect of the sugar not in the products resulting from its digestion but merely in its physical effects on the organism of an infant badly adapted to bear this element of its food. Its action could be best compared to that of salt, the introduction of which into the organism of infants was likewise followed by serious constitutional symptoms accompanied by fever. The one thing impressed on the reader by Finkelstein's stimulating paper is the all-importance of preventing any disturbances of the gastrointestinal tract in children and of treating any occurring disturbance as a serious condition. An infant with a normal gastrointestinal mucosa does not react with any phenomena of disease to the introduction of salts or sugars into its digestive canal, though these substances injected subcutaneously are followed by untoward results. The cells of the mucosa, therefore, have some obscure property of preventing the harmful influence of sugars and salts upon the metabolism of the organism. What this action really is has not been discovered as yet; its prevention, however, lies in the conservation of the integrity of the lining of the gastrointestinal canal of infants, so that alimentary fever may not arise from the mere presence of carbohydrates in the food.

THE ANTIVIVISECTION CRUSADE.

WE note in two current publications some sensible words to which the attention of both the profession and laity may well be directed. The first is the *Journal of Outdoor Life* in which Dr. E. L. Trudeau writes on Animal Experimentation and Tuberculosis. It is due to vivisection, so-called, that we know that the disease is not inherited, but communicable, and, therefore, preventable. "Animal experimentation has taught us already much as to the different types of the tubercle bacillus, its virulence, the poisons it produces, and the manner in which it invades the living organism and destroys it. Slowly but steadily animal experimentation is teaching us the avenues of infection whereby the germ gains access to the organs of its living host; what are the defensive resources of the living organism; and the delicate mechanism whereby it combats the poison of the germ, tries to localize the bacilli, to limit their spread, and ultimately to destroy them. Animal experimentation is teaching us daily more of the complex and delicate processes which bring about acquired and artificial immunity, and through which the living organism wins the victory over the invading parasite. In the thorough knowledge and further study of these vital processes by animal experimentation, lies the hope of applying to the protection of healthy human beings and the cure of disease, the knowledge won by science in studying nature's methods

of cure through long years of tireless and painstaking observations on animals."

The other article appears as an editorial utterance in the *Outlook* of March 6, and is entitled "The Child or the Guinea-pig." This journal says: "It is as impossile for a legislature to prescribe rules for scientific experiments on animals as it would be to prescribe rules for scientific experiments in physics or botany. The laws of natural science do not adjust themselves to the provisions of a statute. The attempt of people to make laws on the subject is in effect an attempt to prevent such experiments. The state of affairs should be squarely faced. . . . The *Outlook* believes in the scriptural truth. 'Ye are of more value than many sparrows,' and believes that the children who have been saved from suffocation by diphtheria are worth thousands of times over all the animals which have served to bring to men the knowledge of antitoxin. The law now confines the right to animal experimentation to those who are competent, as it confines the right of practising medicine to those who are competent. It likewise penalizes the infliction of needless pain on animals, as it penalizes the infliction of needless pain on human beings. If there is ground for complaint against a scientist for the infliction of needless pain in a laboratory, he can be proceeded against under the same laws under which a man may be proceeded against for the needless infliction of pain upon his household pet. There is no reason for singling out the scientific investigator as a subject for class legislation. There are some people who are more concerned for the comfort of a guinea-pig than for the life of a child." Such people, it adds, are beyond the reach of argument. Advocates of new legislation have yet to show that the firm administration of existing laws will not meet every possible emergency. .

THE MODERN HIPPOCRATES.

It is a pleasant custom of many medical societies to invite one of their members or a guest to deliver an address on some general subject at the annual meeting. These addresses, together with the address of the president, serve to relieve the monotony of the purely scientific and casuistic papers, and also, if the orator is fertile in ideas, to interest the members and supply pabulum for thought. Such an address was the one which those present at the annual meeting of the New York State Society in Albany, in January of the present year, were privileged to hear from the lips of Dr. A. Jacobi of this city. In this address, entitled "The Modern Hippocrates" (*New York State Journal of Medicine*, March, 1909), the orator succeeded in presenting a wide survey of the field of medicine, especially of its diagnostic and prognostic divisions, and gave his hearers not only a summing up of the knowledge of the past, but also an optimistic prophetic outlook toward the future, most encouraging as coming from one who has so deep a knowledge of the subject and so wide an experience as a basis for his prognostication.

Space forbids a review of the address, and indeed no review could do it justice, but we may quote the orator's characterization of the modern Hippocrates, who, he says, is to be found in many places throughout the world, for as medicine has grown and widened, so have her followers, practitioners, and teachers. The modern Hippocrates, Dr. Jacobi says, "amasses learning and delights in science; is equally patient and painstaking in study, on the platform, and at the bedside; and scrutinizes the patient both for what the sick may add to his knowledge and what he may add to the comfort and welfare of the sufferer. While being searching and exact, he is conscientious and full of pity. He is equally joyful over restored health and over a new fact revealed by investigation guided by erudition and genius. That he will gladly publish; but he is seldom a text-book writer. He enjoys new truths discovered by himself or others; he is no priority hunter and is anxious to give credit. His character is full of simplicity, fidelity and loyalty; loyalty to his duties toward the individual, the hosptal, and his pupils. He is the revered teacher of young and old, and a friend to the young colleagues in whom he honors the future of medicine. That is why they feel at home with him though, or because, he is a celebrity on both sides of the ocean. Gossip and low strifes do not reach him. His prototype, old Hippocrates, told him that 'disputes among doctors cause disrespect of the whole art among the people, so that they begin to doubt the reality of medical art.' In his practical work he is nobody's antagonist. His competition is judicious and gracious and guided by the unwritten code of ethics inscribed in his soul. That of the just he invites, that of the unjust he endures with forbearance. Still greater than as a physician he is as a man and a citizen. His eminent place in science and the community he utilizes in the service of the commonwealth. He is its adviser as a sanitarian, who augments for the millions both health and wealth. In that sense, as our modern requirements and responsibilities have grown and persist in growing, his opportunities and labors and his results exceed those of his older brother, Hippocrates of Hellas."

LENGTH OF STAY IN BED AFTER LABOR.

It has been the general agreement among obstetricians that patients should stay in bed from seven to ten days after parturition, so that the uterus may have time to reassume partly at least its usual condition and the small injuries occasioned by the act of labor may have a chance to heal. But just as a number of other seemingly well-founded customs have been attacked of late, so this universal custom of keeping parturient women in bed for a certain length of time has found a number of opposers. Küstner proposed several years ago to allow women to leave their beds a day or two after parturition, but at that time he was overwhelmed with the condemnation of all experienced obstetricians. Gradually, however, a number of men began to follow the suggestions made by Küstner, and in the *Münchener medizinische Wochenschrift* for February 9, 1909, Karl Mayer tells the results observed with this

method at the Marburg Clinic for Women. He did not insist upon any hard-and-fast rule compelling the women to leave the bed a stated number of days after labor, but simply allowed the patients to get up as soon as they expressed a willingness to do so. His experience was that all the patients preferred to remain in bed the first two days, resting from the physical and psychic strain of parturition. Four women left their beds on the third day, ten times as many on the fourth day, while over a hundred arose on the fifth day. The usual examination at the time of discharge showed no unusual results so far as the position and size of the uterus were concerned, about the same number of displacements and subinvolutions being found as when the custom was to insist upon a week or ten days' stay in bed. A few women suffered from retention of lochia, but simple remedies sufficed in all cases to do away with the unpleasant consequences of such retention, and, moreover, these accidents were quite frequently encountered in the case of women resting over ten days in bed. No more serious consequences than a slight fever were ever noted.

The most important effects of leaving the bed early were noted in the general condition of the patients, the morbidity among these women being lower by over 10 per cent. than in a similar number of previous cases. Mayer concludes in general that there is no reason for keeping women in bed after labor if they feel strong enough to sit in a chair or be up and about, but there is a good deal of danger in prescribing any stated number of days after which normal patients need no longer stay in bed. The cases must be individualized, the general condition of the patient being a good criterion for a decision in the matter. The one great advantage in allowing patients out of bed as early as possible consists in the fact that many of the women who are compelled to work almost as soon as they leave the institutions find themselves much stronger if they have been up and about for a few days before beginning such work. The old rule of ten days in bed and a discharge from the institution after one day out of bed left the women of the poor in no condition to work on reaching their homes. That contraindications exist to leaving the bed early is of course self-evident; among these Mayer mentions gonorrheal infection, important injuries to the birth canal, whether recent or old, and extreme youth of the mother.

Tuberculin in the Tuberculosis of Infants and Children.

It is probable that no remedy has had such an uneven history as Koch's tuberculin. Hailed at first as a specific for tuberculous infections of all kinds and in all individuals, it was soon dropped almost completely by the medical profession, after the early indiscriminate use of it showed no immediate curative effects and in many cases hastened the course of the disease. It then became quite popular as a diagnostic measure and only slowly the therapeutic use of the remedy reassumed its right of existence among the antituberculous remedies at our command. Lately the introduction of the cutaneous and conjunctival reactions has popularized tuberculin still further and it may be correctly said that tuberculin is now more frequently employed than at any time since its introduction. The therapeutic effects of the drug are quite generally granted; the indications for its use and the dosage to be employed are still a matter of dispute, and the only way to settle this is to study the results obtained by careful observers with various methods of applying tuberculin. In this connection a paper by the noted German pediatrician, Arthur Schlossmann, printed in the *Deutsche medizinische Wochenschrift* for February 18, 1909, is of great interest. Schlossmann shows in this paper that notwithstanding the very serious prognosis of tuberculous infection in early infancy, such infection need not necessarily be fatal if tuberculin is persistently used in doses sufficient to produce a moderate reaction characterized by fever. Under such treatment the affected children recovered their usual well-being, gained weight, successfully overcame local manifestations of infection, such as tuberculous disease of the phalanges and other bones of the extremities, and passed safely through the first ten to eighteen months of life. At the same time other children who received the same hygienic and dietetic treatment, but were not given tuberculin, succumbed to the disease very rapidly after the infection became manifest. The dosage used and the prolonged administration of the remedy are somewhat different from the manner of employing tuberculin in extremely minute amounts recommended by many authorities of late. The one point of importance is the fact that these very young children treated with tuberculin survived the infection; of course their future fate cannot be surmised, but the mere fact that they did not succumb in early infancy, but showed instead progressive and rapid amelioration of the symptoms of the disease and improvement in the general health is enough for calling attention to the results obtained by Schlossmann. Beyond the clinical evidence of success he was able to demonstrate that the formation of antibodies runs parallel with the administration of relatively large doses of tuberculin as soon as tolerance for the remedy has been established by the use of very small doses for a protracted period. The specific influence of tuberculin in such cases was therefore indubitably proved, and as the dosage adopted by Schlossmann led to good clinical results it may well be imitated by other physicians who are confronted with the difficult task of treating infants and children suffering from tuberculosis.

Pneumococcus Influenza.

Ever since the great pandemic of influenza in 1889 and 1890 the bacillus isolated by Pfeiffer from the nasal and bronchial secretion of patients has been looked upon as the true excitant of the disease in question. There occur, however, numerous cases quite apart from epidemics which clinically answer fully to true influenza, and yet the Pfeiffer organism seems to have nothing to do with the causation, being absent during the entire course of the affection. It would seem therefore that if the term influenza is to be retained for the disease caused by the influenza bacillus some other designation must be adopted for the disease of a similar clinical course that is not due to the bacillus in question. In the *Münchener medizinische Wochenschrift* for February 23, 1909, Curschmann of Leipzig describes a number of cases of grip that have occurred in Germany during the last two years run-

ning the typical course of the disease caused by the Pfeiffer bacillus. In the great majority of the cases, however, careful bacteriological examination of the sputum showed that the causative organism was the pneumococcus of Fraenkel-Weichselbaum, an organism which is usually looked upon as producing a typical lobar pneumonia when it infects the human body. Curschmann's patients complained of initial chilliness accompanied with headache and intense muscular pain; their appetite suffered from the onset of the disease; prostration was greatly marked when the short duration of the symptoms is considered; the pharynx usually showed slight inflammatory conditions accompanied by soreness, hoarseness, etc. In a word, there was no suggestion whatever of the clear-cut picture of lobar pneumonia with its intense initial chill, high fever, nervous symptoms, and the critical fall of temperature a few days after onset. The number of examinations was such that an incidental presence of the pneumococcus must be excluded and the conclusion of Curschmann declaring that a disease quite similar to the influenza caused by the Pfeiffer bacillus could be due to the pneumococcus must be accepted. His observations are of interest in explaining the etiology of the cases that often come to the hospital with suspected pneumonia, but run a clinical course of influenza-like character and show rapid subsidence of all symptoms. The difficulty with medical nomenclature is, likewise, brought out by his findings, for they show the fallacy of naming infectious diseases according to the exciting organism alone. The same organism may produce distinctly different clinical conditions, and two or more distinct organisms may produce diseases with practically identical clinical symptoms. In such cases one and the same name will not always convey a correct mental picture of the disease.

News of the Week.

Influenza Epidemic.—London reports a number of cases of influenza and pneumonia, accompanying the disagreeable raw weather which has been prevalent. For the week ending March 11, there were 66 deaths from the first-named disease, as against 36 for the previous week, while 314 deaths from pneumonia were reported, and 348 from bronchitis. Some of the large business firms report that 4 or 5 per cent. of their employees are ill. St. Petersburg has suffered severely and so has Berlin, so that it seems that a new and severe epidemic is about to visit the countries of the West.

Smallpox in Canada.—An outbreak of smallpox has been reported among the half-breeds in the Cypress Hills south of Medicine Hat, Alberta, but a few miles to the north of Montana.

Typhoid Fever in Spain.—Madrid has been visited by an epidemic of typhoid fever. Up to March 11, over three hundred cases had been removed to hospitals, and many deaths had occurred, though the exact number was not ascertainable.

Mills to Fight Tuberculosis.—The State Health Department having brought the matter to their attention, more than twenty manufacturing companies in Worcester, Mass., have enlisted the support of their twelve thousand employees in a campaign to stamp out tuberculosis in that city. Each firm has agreed to pay the expenses of three months' treatment at the Massachusetts State Sanatorium, at Rutland, of any employee who may be suffering from the disease in its early stages. The State health inspectors argue that it is the duty, from an economic as well as from a humane standpoint, of the manufacturing concerns to help in the movement, since the mills from the nature of the work and the confinement of the employees are sources of infection, and the illness of one of the employees not only lessens his productive capacity but also endangers the health of other workers.

New Tuberculosis Clinic.—The second tuberculosis clinic to be established in the Borough of Brooklyn was opened for inspection on Monday evening, March 8, at the Bay Ridge Hospital and Dispensary, Sixtieth street and Second avenue. The Department of Health maintains a similar clinic in the lower part of the city, but the new one is the first to be established by private means. The clinic has been fitted up by the New Utrecht Red Cross Society acting in conjunction with the Ladies' Auxiliary of the hospital. The visiting staff will be composed of Dr. Frank E. Stoney, Dr. Robert E. Coughlin, and Dr. Rollin Hills. Dr. S. Adolphus Knopf of New York was the guest of honor at the opening reception.

Texas State Sanatorium.—The Legislature of the State of Texas on March 11 passed a bill appropriating $200,000 for a State sanatorium for indigent patients suffering from tuberculosis. An effort will be made, it is said, to acquire title to Fort Clark, a military post in western Texas which is soon to be abandoned by the United States.

Site for State Colony.—A site for the Eastern New York Custodial Asylum, a new State colony for defectives, has been selected at Thiells, Rockland County, by the commissioners who were appointed for the purpose, in July, 1907. Title has been taken to much of the land, and a preliminary plan for the institution has been developed. The commission in its report to the Legislature recommends that the name Letchworth Village be given to the colony in recognition of the distinguished services of William Pryor Letchworth in behalf of the defective wards of the State.

American Hospital in Paris.—Through the interest of members of the American colony in Paris, funds have been collected with which two adjoining villas at Neuilly, a suburb of the city, have been purchased and transformed into a perfectly equipped hospital, containing two wards of seven beds each, eleven private rooms, and a consulting room. The institution which is designed for the use of all classes of the growing American colony, as well as for tourists, will be formally opened in May, and will fill a long felt want, because of the formalities which must be complied with before Americans can gain admission to the French hospitals.

St. Anthony's Hospital, Rockford, Illinois, elected the following staff of physicians at its organization meeting, held February 26: *President,* Dr. W. G. Hatch; *Vice-President,* Dr. Emil Lofgren, and *Secretary-Treasurer,* Dr. Geo. P. Gill.

Charitable Gifts.—Dr. Martin H. Boyé, whose death was noticed last week, bequeathed to the University of Pennsylvania, from which he was graduated in 1844, the sum of $12,000 to be used for the University hospital.

The Rhode Island Hospital at Providence, R. I., receives a bequest of $4,000 by the will of the late Mrs. John Carter Brown, for the endowment of a bed in memory of her sister.

The Foundling Hospital of New York will re-

ceive about $6,000 by the terms of the will of the late Mrs. L. T. Campbell who died recently in Denver.

Medical Department at the University of Wisconsin.—A bill to abolish the medical department in this University was recently voted down in the State Legislature. The University has at present a two-year course, the student going elsewhere for the other two years.

A Pekin Medical College.—The Chinese Emergency Appeal Committee, of which Sir Robert Hart, formerly Inspector General of Customs in China, is president, has issued an appeal for $500,000 for the purpose of developing a medical college at Pekin, and three medical schools elsewhere in the empire. The scheme is to provide a thorough medical training for the Chinese on modern lines, including the translating of the best Western text books into Chinese.

"American Journal of Surgery."—The Greater New York number of this journal, issued this month, is a noteworthy contribution to current medical literature. The entire subject matter of the number has been contributed by New York surgeons, and several new operations are described for the first time. Among the contributions are: "Intestinal Resection; a Preliminary Report of a Simplified Method," by Howard Lilienthal; "Sigmoiditis and Perisigmoiditis," by James P. Tuttle; "Sacral Suspension of the Uterus, a New Technic," by John Van Doren Young; "Cancer of the Breast," by Willy Meyer; "Surgery of Foreign Bodies, with Especial Reference to Those Occurring in the Skeletal Tissues," by Walter M. Brickner; "The Operation of Direct Blood Transfusion," by John A. Hartwell; "The Avoidance of Hemolysis in Transfusion," by Martin Rehling and Richard Weil; "Fibrosis Uteri and its Surgical Treatment by a New Method," by Samuel W. Bandler; "Dislocation of Cervical Vertebræ," by James P. Warbasse; "A Plastic Mastoid Operation," by Frank Tucker Hopkins; "A Modified Operation for Inguinal Hernia," by Albert E. Sellenings; "Surgery of the Pericardium and Heart," by H. Beeckman Delatour.

To Bar Japanese Doctors.—A bill has been introduced into the Territorial Assembly of Hawaii making it imperative that applicants for license to practise shall pass the examination given by the Territorial medical examiners in the English language. It is said that the Hawaiian Medical Society is back of the bill, which is aimed to prevent the admission of Japanese doctors.

Court Enjoins Physician.—A decision which had no precedent in the State of Massachusetts was handed down by Judge Morton in the Supreme Court of that State recently, when he issued a permanent injunction restraining one physician from practising in Brookline during the life time of another physician, unless he conformed to an agreement entered into by the two physicians in 1906. The agreement which was signed when the enjoined physician began his duties as assistant to the other, provided for the mutual benefits to be received under the contract, and also provided that in the event of the breaking of the agreement the assistant should not practise in the town during his employer's lifetime. A few months ago the agreement was broken and the assistant started in to practise for himself. Hence the enjoinment.

A Discussion on Ethics and Fees in Chicago.—At a meeting of the Physicians' Club of Chicago, held March 11, with Dr. Wm. T. Belfield in the chair, the following subjects were discussed, a good deal being said pro and con: Business Partnerships in the Medical Profession; the Question of the Division of Fees; Advantages and Disadvantages of Office Cooperation and Business Partnership among Medical Men; The Question of the Division of Fees from the Surgeon's Standpoint; An Equitable Arrangement of Fees from the Physician's Standpoint. The speakers were Drs. Casey A. Wood of Chicago, J. F. Percy of Galesburg, Ill., Wm. E. Quine, Henry F. Lewis, Charles L. Mix, John A Robison of Chicago, and J. W. Pettit of Ottawa, President of the Illinois State Medical Society.

Board of Health Demands.—To provide additional accommodations for tuberculosis patients in advanced stages, the New York Board of Health has asked for $500,000 from the Board of Estimate. It is planned to spend $100,000 of this in building four additional pavilions at the Riverside Hospital on North Brother Island, thus doubling the capacity of the institution, where about two hundred patients are already housed. A like sum will be used in the erection of four pavilions at Otisville, each accommodating sixty patients. Of the balance, $250,000 will be expended for a plant in Queens, which will include pavilions for the accommodation of several hundred patients, as well as an administration building and all the necessary equipment of a good hospital.

Memorials to the Late Dr. William T. Bull.—Already the friends and associates of Dr. Bull are planning for a fitting memorial to the great surgeon, and a meeting of some of them was held recently at the home of Dr. L. Bolton Bangs to discuss the form such a memorial might take. As a result of the meeting an executive committee has been appointed to take up the work immediately. The committee is at present composed of Mr. John E. Parsons, Hon. Joseph H. Choate, Mr. Austen G. Fox, Dr. Clement Cleveland, Dr. Virgil P. Gibney, Dr. Francis P. Kinnicutt, Dr. Nathaniel Bowditch Potter, Dr. John B. Walker, and Dr. L. Bolton Bangs. While definite plans have not yet been formulated, it is probable that the memorial will take the form of an institution for surgical research to be connected with the College of Physicians and Surgeons, New York, from which Dr. Bull was graduated in 1872, and where he served for many years as Professor of Surgery.

A despatch from Savannah reports that Mrs. Bull authorizes the statement that she intends to erect a hospital as a memorial to her late husband. The hospital will be for the treatment of tuberculosis and the study of the disease. It will be amply endowed and will be under the direction of tuberculosis specialist. The amount of the endowment, the location, and other details will be announced in a short time.

Dr. James C. Hepburn, the oldest living graduate of Princeton, and for many years a medical missionary in Japan, celebrated his ninety-fourth birthday on March 14, at his home in East Orange, New Jersey. Dr. Hepburn was graduated from Princeton in 1832, and from the medical department of the University of Pennsylvania in 1836. After a few years of practice in New York, he joined the medical staff of the Presbyterian Board of Foreign Missions and devoted himself to the work in Japan.

Testimonial to Dr. Charles K. Mills.—A banquet was tendered to Dr. Charles K. Mills, Profes-

sor of Neurology in the Medical Department of the University of Pennsylvania, on the evening of March 13, in celebration of the fortieth anniversary of his entrance on the practice of medicine, and he was presented with a silver loving cup. Dr. George E. de Schweinitz acted as toastmaster and toasts were responded to as follows: "Personal Recollections of a Friendship," by Dr. S. Weir Mitchell; "Doctor and Parson," by Rev. Arthur B. Conger; "Reminiscences of the American Neurological Association," by Dr. James J. Putnam; "The General Practitioner," by Dr. Abram Jacobi; "Relation of Neurology to Pathology," by Dr. Wm. H. Welch. The presentation of the loving cup was made by Dr. W. W. Keen, and Dr. Mills responded. The committee in charge of the banquet consisted of Drs. W. W. Keen, Wharton Sinkler, James Hendrie Lloyd, Francis X. Dercum, Wm. G. Spiller, and David Riesman.

Fees of the McKinley Surgeons.—The Treasury Department recently made public a statement covering all of the items of expenditure incident to the last illness of President McKinley, under the appropriation of $45,000 for this purpose, made by Congress on July 1, 1902. The payments to the physicians, as the records appear on the Treasury ledgers, follow: Dr. M. D. Mann, $10,000; Dr. H. Mynter, $6,000; Dr. C. McBurney, $5,000; Dr. Roswell Park, $5,000; Dr. C. G. Stockton, $1,500; Dr. E. G. Janeway, $1,500; Dr. H. G. Matzinger, $750; Drs. W. W. Johnston, E. W. Lee, and H. R. Gaylord, $500 each; Dr. N. W. Wilson, $250; Dr. G. McR. Hall and Dr. E. C. Mann, $200 each.

Silver Bow County (Mont.) Medical Society, at its annual meeting on February 24, elected the following officers for the ensuing year: *President,* Dr. John A. Donovan; *Vice-President,* Dr. Peter Potter; *Secretary,* Dr. Phoebe A. Ferris; *Treasurer,* Dr. T. E. Blackburn; *Delegates to the State Convention,* Drs. Pigot, Ferriss, Renwick, Kingsbury, Stokes, and Matthews.

The Outagamie County (Wis.) Medical Society, at its annual meeting on March 2, elected the following officers: *President,* Dr. J. H. Doyle of Little Chute; *Vice-President,* Dr. E. Bayer of Appleton; *Secretary-Treasurer,* Dr. M. J. Sandborn of Appleton; *Censor,* Dr. J. J. Laird of Black Creek.

The New Bedford (Mass.) Medical Society held its third annual dinner on March 1. Addresses were made by Dr. Henry A. Christian, Dean of the Harvard Medical School, whose subject was Modern Methods in Medicine as Illustrated by Recent Work on Nephritis; Dr. Maurice Richardson, who spoke on Early Diagnosis of Surgical Lesions; and Dr. Homer Gage, whose subject was the Negative Side of the Emmanuel Movement.

The Late Dr. A. J. McCosh.—At a regular meeting of the New York Surgical Society, held March 10, 1909, the following resolutions were unanimously adopted by the Society:

Whereas, Death removed from the roll of this Society, on December 2, 1908, our distinguished colleague, Dr. Andrew J. McCosh; and

Whereas, During the many years of his membership in this Association, Dr. McCosh has been an active worker, an ardent and enthusiastic supporter of the objects which called the Society into being; and

Whereas, By his formal communications and presentation of rare and interesting clinical cases, as well as by his illuminating discussions, he has added much to the interest of our meetings; and

Whereas, During the entire period of his professional activity, Dr. McCosh stood for the highest ideals, and has ever maintained the loftiest standards of professional ethics; be it

Resolved, That in the death of our honored colleague, the New York Surgical Society has lost one of its most valued fellows, who, by reason of his unusual ability, his extraordinary technical skill, his wise and conservative judgment, his untiring energy, and his devotion to his professional work, has made for himself a conspicuous position in the foremost ranks of the world's surgeons; and who, by his modesty, his professional integrity, his kindliness, and his generous treatment of the poor and unfortunate who came under his care, has endeared himself, not only to the medical profession, but to the entire community in which he lived; be it further

Resolved, That these resolutions be spread upon the minutes of this Society, and a copy be transmitted to the family of our deceased colleague and to the weekly medical journals of this city for publication.

George E. Brewer.
Ellsworth Eliot, Jr.
Clarence A. McWilliams,
Secretary.

The Late Dr. W. T. Bull.—At a regular meeting of the New York Surgical Society, held March 10, 1909, the following resolutions were unanimously adopted by the Society:

Whereas, William Tillinghast Bull, M.D., was removed by death from the roll of the Society on February 22, 1909;

Whereas, By his death not only the New York Surgical Society, but the community and the world at large have suffered a great loss; and

Whereas, The New York Surgical Society desires the opportunity to express its sorrow and its appreciation of his character and attainments; be it

Resolved, That the Society, collectively and individually, mourns the loss of one who, by his sympathy, geniality, gentle modesty, and untiring devotion, was endeared to all; and who, by his wisdom, judgment, and brilliant execution, occupied the foremost rank among the surgeons of the world; and further, be it

Resolved, That these resolutions be spread upon the records of this Society and a copy be forwarded to his bereaved family and to the medical journals.

George Woolsey.
George E. Brewer.
Samuel Alexander.
Joseph A. Blake.
Clarence A. McWilliams,
Secretary.

Physician, Soldier, Priest.—Brigadier-General William Adams Olmsted, who until recently was chaplain of St. Elizabeth's Hospital, New York, died on March 9, aged 74 years. General Olmsted was graduated in medicine from the Howard University of Washington, D. C., but in 1861 was made captain of the first company of volunteers raised in New York. He fought through the war with great distinction and on the disbandment of the army had reached the rank of brigadier-general. After serving for a number of years as a physician among the Indians, General Olmsted took holy orders at Notre Dame University, Indiana, about ten

years ago. He had acted as chaplain at St. Elizabeth's Hospital since that time until last January when he suffered a stroke of paralysis.

Mr. Thomas Wakley, editor of the *Lancet* and grandson of the founder of that journal, died in London, on March 5, at the age of 57 years. He was educated at Cambridge and was a Licentiate of the Royal College of Physicians.

Obituary Notes.—Dr. Charles F. Caverly of Boston, Mass., died at his home of Bright's disease on March 6. He was a graduate of the Phillips Exeter Academy, Harvard University, and the Dartmouth Medical School.

Dr. Edwin D. Wiley, one of the pioneer physicians of Des Moines, Iowa, died suddenly on February 27, while attending a patient. Dr. Wiley was born in Canada in 1846, and was graduated from the Bennett Medical College of Chicago in 1870. He was a member of the American Medical Association, and a prominent Mason.

Dr. Frank Jackson McNett of Traverse City, Mich., died at his home on February 28, of pneumonia, at the age of 38 years. Dr. McNett was graduated from the Bellevue Hospital Medical College, New York, in 1898, and had made a special study of diseases of the eye, ear, nose, and throat. He was a member of the American Medical Association.

Dr. William H. Sage of Woodbury, Conn., died at his home on March 10, aged 84 years. Dr. Sage was graduated from the Yale Medical School in 1849, and had practised in New Haven until his retirement a few years ago.

Elias C. Kitchin died at Brumfieldville, Pa., on March 13, at the age of 82 years. He was graduated from the Vermont Academy of Medicine in the class of 1850.

Obituary.

THADDEUS ASBURY REAMY, M.D.

CINCINNATI, OHIO.

Dr. Thaddeus Asbury Reamy of Cincinnati, Ohio, died at his home on March 11, in his eightieth year. Born in Virginia, in April, 1829, Dr. Reamy studied medicine at the Starling Medical College, at Columbus, Ohio, from which he was graduated in 1854. Five years later he was appointed professor of materia medica and therapeutics in the Cincinnati College of Medicine and Surgery, a position which he held for only two years, resigning in 1861 to enlist as a surgeon in the 122d Ohio Volunteer Infantry. In 1863 he was made professor of the diseases of women in the Starling Medical College, and, in 1871, professor of obstetrics and the diseases of women and children. In 1888 he became professor of gynecology in the Medical College of Ohio, now the Medical Department of the University of Cincinnati. Dr. Reamy had served since 1871 on the gynecological staff of the Good Samaritan Hospital of Cincinnati, and was on the staff of the Cincinnati Hospital from 1880 to 1898. He was a member of the Cincinnati Academy of Medicine, of which he was president in 1877, of the Ohio State Medical Society, of the American Medical Association, of the Cincinnati Obstetrical Society, of the American Gynecological Society, and of the Southern Surgical and Gynecological Society. He had written frequently for various journals on gynecological subjects, and was a contributor to Mann's American System of Gynecology.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE CARNEGIE TRUST, BIOLOGY—ROYAL COMMISSION ON THE UNIVERSITY—DISEASES OF STOMACH—CANCER RESEARCH AT THE MIDDLESEX AND CANCER HOSPITALS—OBITUARY

London, February 26, 1909.

The importance of original research has been brought prominently before the public by a speech by Mr. A. J. Balfour at the seventh annual meeting of the Carnegie trust for endowment of research in the Scottish universities. The meeting was held in London on Wednesday and the report reviewed the whole work of the trust during the seven years of its existence. The report of the work in the biological and medical sciences was presented by Dr. Dobbie of the Royal College of Physicians, Laboratory, and the reports of other departments were by those who had supervised them. Mr. Balfour referred chiefly to the encouragement of research and said there was no greater waste than the waste of brains, intellect, originality, and of the scientific imagination. They needed to catch the men possessed of these, and therefore of capacity for carrying on original investigations, to catch them before they got absorbed in professional life, in order to extract from them all they could in the way of invention and originality. There was also a rarer class of men, who seemed born for research, to whom the penetration into the secrets of nature was an absorbing passion from which they would not be diverted except by the absolute necessity of obtaining their daily bread. It was all important that those men—not for their own sake, but for the sake of the community—should have a chance of devoting their rare talents to the great work for which God undoubtedly intended them, and Mr. Carnegie's trust had aided many such to add to the knowledge which was the heritage of all civilized mankind. He therefore deserved the thanks of the whole civilized world.

Royal commissions offer to governments good opportunities of acquiring solid information on abstruse subjects. They are also useful to politicians as a means of shelving inconvenient questions. We have had a free recourse to them of late and some people are saying they do not want to be governed by them. The last was announced on Saturday and is a new one on the University of London. It had been expected for some time, a promise having been made when the Imperial College of Science was founded, that if after a time the Senate desired it such an inquiry should be made as to the incorporation of the college in the university. The Senate passed a resolution to that effect on December 2 last, whereupon the London medical schools united in representing to the Government that the medical department and medical education should also be considered. The new commission's reference includes this, and as the faculty of medicine has always overshadowed all others in importance—at any rate up to the last reorganization in 1900—we may hope that possibly London will at last possess a university which the profession can regard with satisfaction. Since 1900 it has been a teaching body (of a sort) and some departments may have made progress, but not the medical. The teaching seemed to consist for the most part in authorizing a number of peripatetic lecturers on various subjects and rather resembled the "extension scheme" of the older universities than any essential part of those bodies. Up to 1900—the so called London University was a mere examining body and endeavored to keep up its status by piling on the subjects and increasing the severity of its examinations. It failed egregiously to produce scholars, physicians, or surgeons. Not that such men did not pass the tests, but it is now recognized that they would have done very well without diplomas, which only signified ability to absorb knowledge and disgorge it with facility. To keep up the standard regulations were insisted on as to the particular order of study. No one, for example, could be admitted to any medical examination unless the whole of his curriculum was filled in after the matriculation. So a student who had been a session or more engaged in anatomy, chemistry, etc., must take that matriculation and attend again lectures on those subjects. Many a one did not know of such a rule. Many a parent hesitated at the extra expense of keeping his son an extra year in London and many a teacher advised him not to do so. You might see men who

declined to be thus driven holding classes for the higher examinations of the university, or rather examining board, whose lowest degrees were to them unattainable.

In his second Lettsomian lecture Dr. S. Martin dealt mostly with the motor power of the stomach, which is often affected in disease, especially in the direction of diminishing of that power which leads to dilatation. This is often the base of chronic dyspepsia resulting from irritation, insufficiency or obstruction to the expulsion of the contents. It plays so great a part as the main symptom that the diagnosis between functional dilatation and that due to organic disease is of the greatest importance. In hyperchlorhydria there may be no motor deficiency for months or years in some cases, but in others dilatation may occur early. It may be detected by the stomach tumor, the succussion splash and auscultatory percussion which will determine the area occupied by the organ. Inflation of the stomach would also serve as by letting the patient drink solution of bicarbonate of soda (30 grs. to 4 or 5 oz.) and a corresponding quantity of tartaric acid solution. A normal stomach would hold 35 oz. as an average, but there are considerable variations. The amount may be estimated by making the patient drink as much liquid as he can tolerate without distress and then seeing how much can be siphoned off. Signs of slight dilatation are common in functional disorders, particularly in gastric insufficiency and nervous dyspepsia. Some spoke of myasthenia, but the lecturer did not use that term when symptoms of dilatation coming on after meals disappeared in four or five hours, and so appeared to be temporary. But if the conditions continued it would become permanent. The lecturer was of opinion that even great dilatation might be the result of only functional disorder. This was important to remember, as operative measures might otherwise be suggested when milder means would suffice. Passing on to gastroptosis, he said it was sometimes associated with enteroptosis and movable kidneys as well as prolonged symptoms of dilatation, though the secretory activity might be normal. With regard to the causes of gastric irritation, the first place was assigned to imperfect mastication, bolting the food, and bad teeth. Then the food itself as to both quantity and quality had to be considered, the time of taking it too, irregular meals, the rush and worry of modern life and work immediately after eating, excitement, or, on the other hand, sedentary habits—all these combined to interfere with digestion, and proper regulations of remedying these things were the remedy for their consequence. Besides these, chronic bacterial sources of irritation were pyorrhea alveolaris, disease from the nasal passages and antra, and chronic tonsillitis, etc., the discharges passing into the stomach and poisoning the body. Intestinal infection was also to be admitted. There might also be deficient activity of all the organs of digestion. The lecturer then proceeded to consider nervous dyspepsia, a group difficult to deal with, as cases might closely resemble organic diesase, and when differentiated might resist treatment. The cases varied so much that at one end of the line signs of mental disease or profound neurasthenia with stomach symptoms were presented; at the other end the nervous symptoms almost replaced the functional indigestion first observed. But many cases which he wished to speak of next showed great exaggeration of one or other of the symptoms of functional disorder, as flatulence, eructation, hiccough, vomiting, pain, dilatation, emaciation—any one of these might be the most prominent, absorbing the attention, but with it reflex nervous symptoms, such as headache, palpitation, dyspnea and extreme lassitude, both mental and bodily. In the family history often migraine, epilepsy, asthma, nervous breakdown, or mental disease. Abrupt changes of these symptoms as to approach and cessation are very common. Some points respecting these may help. Flatulence was caused by any of the sources of irritation, was present in all cases of dilatation and in bacterial decomposition. But the flatulence in nervous dyspepsia differed very often in its explosive character, its sudden onset without apparent cause, and the great quantities of gas brought up. The lecturer attributed the accumulation of gas, apart from bacterial fermentation, to the air and saliva swallowed, to regurgitation of alkaline liquid from the intestine, and to the discharge of gas into the stomach from the blood. Any one or more of these causes might set up the flatulence of nervous dyspepsia. Eructation of liquids was frequent in these cases, but not in organic disease. Vomiting coming on frequently after meals, but not always without pain in the abdomen, was functional, though it might last for long periods and lead to great emaciation. Yet there might be no alteration of the secretory power. Pain was difficult to gauge. It might be localized in the epigastrium, suggesting organic disease, but perhaps shift to another spot quite suddenly and would disappear on the supervention of headache or neuralgia. Tenderness might also be present, adding to the difficulty of diagnosis. But several tender spots over the abdomen indicated a nervous and not an organic origin. The diagnosis from ulcer of the stomach when pain was severe could sometimes be made from the absence of vomiting, the shifting character of the pain, the presence of several tender spots on the interchange of the pain with pains in other parts; these were all symptoms of functional disorder and not of organic disease. Attention was then drawn to cases in which severe headache was a constant symptom of nervous disorder of the stomach. This headache must be regarded as a reflex nervous symptom, for, although the stomach symptoms might be slight and the intense headache the prominent feature, it was amenable to proper diet and rest, and sedatives were not necessary, and were to be avoided.

Yesterday at the annual meeting of the Middlesex Hospital Mr. Gould, senior surgeon, in the chair, a briel account was given of the work of the cancer laboratories by the director, Dr. Lazarus Barlow. They were opened in 1900, and he showed that really valuable work had been done in them; in fact, the annual reports prove that, although the impatience of some is a hindrance. The cancer question, he said, is bound up with the laws of growth, and though infants have grown into adults for untold years, practically nothing is known of the laws governing that growth. So it is with cancer. A ship would be a long time building if the workmen had had to quarry the ore for the iron and fell the trees. Some day the early steps in the investigation of cancer will have been finished and the cause discovered, and that will be the greatest step toward cure. Nothing would give the staff greater joy than that the Middlesex Hospital, which had led the way in research, should show the way to the discovery of a cure. Two thousand five hundred pounds sterling a year is little to keep 10 highly qualified scientists at the work to find a cure for a disease claiming 30,000 victims a year in England and Wales alone. It is unthinkable that this work should stop for want of money.

At the annual meeting of the Cancer Hospital, Mr. Jessett, replying to a vote of thanks to the staff, said that operations which 25 years ago were thought impossible were now done with a mortality of only a little more than 3 per cent., though many were very severe. But still the Registrar General's report showed an increase in the deaths from cancer. The board had not shrunk from spending money on the research department and had secured the services of the most able men to be obtained, with a result that there had been great strides. Of late there had been a great boom about radium treatment, but in that hospital they had been using radium for six or seven years. It was, however, too early to speak of results. They must wait to see if the disease recurred in patients who were apparently cured. But they all hoped much from radium.

Sir John Watt Reid, K.C.B., late Director-General of the Navy Medical Department, Honorary Physician to the King, died on Tuesday in his 86th year. He graduated at Edinburgh and entered the service in 1845. He served during the Russian War in the Black Sea in 1854-55 and received the Crimean and Turkish medals; later in the China War, 1857-59, received the medal with clasp, and in the Ashanti campaign, 1874, was mentioned in dispatches. Sir John was appointed Director-General in 1880 and Honorary Physician to Queen Victoria in 1881; made K.C.B. (military) in 1882, and retired, after 43 years' service, in 1888. His university made him LL.D. in 1884.

Dr. H. W. King, physician to the Chester General Infirmary, died yesterday, aged 53. He graduated M.D at Edinburgh in 1888, having taken the College of Surgeons' diploma in 1878. He held an excellent position among his brethren and was president of the Chester Medical Society. He was also Surgeon-Lieutenant-Colonel in the Volunteers.

Prof. David James Hamilton, F.R.S., who recently resigned the chair of pathology at Aberdeen, died on Friday, the 10th inst. He was educated at Edinburgh, where he graduated (1878) after taking the diplomas of the two colleges (1870), and made demonstrator of pathology. He also studied in Vienna and Strassburg,

and became assistant professor of pathology at Edinburgh University and pathologist to the Royal Infirmary. In 1882 he accepted the full chair at Aberdeen, where his memory will long be cherished for his great teaching power, as well as his original contributions to his favorite science. His textbook, too, will long be authoritative.

Dr. C. J. F. Routh, who long held a distinguished position among London gynecologists, died on the 19th inst. at the age of 87. He was a son of Sir Randolph Routh, K.C.B., and was educated in London, Paris, and Vienna. He took the M.R.C.S. in 1843, M.R.C.P. in 1859, was consulting physician to the North London Hospital, a corresponding fellow of the academies of Madrid and Pesth and of the Gynecological Society of Boston, U. S. A. He contributed many papers to the societies and journals.

Mr. George Edward Walker, F.R.C.S., of Liverpool, died on the 15th inst., aged 70. He was founder and surgeon of the Eye and Ear Hospital and a recognized authority in ophthalmic surgery. He had been a vice-president of the Liverpool Medical Institution and contributed various papers to the ophthalmological transactions and other journals.

Dr. Lindsay Steven of Glasgow died suddenly on the 14th inst. in his 51st year. He was physician to the Western Infirmary, and had held many other offices. He had been for a long time a favorite teacher of pathology. Indeed, from the time he took his degree (1884) he had devoted himself to that subject, and his writings stamped him as one of the foremost pathologists of the day. As a clinical physician he was also a great success. He had been a member of the General Medical Council. For 10 or 12 years he was one of the editors of the *Glasgow Medical Journal*.

Glasgow has lost another leader in Henry E. Clark, late surgeon to the Royal Infirmary and Professor of Anatomy in St. Mary's College. He edited "Wilson's Anatomy" and for some years the *Glasgow Medical Journal*. He was president of the Faculty of Physicians and Surgeons from 1903 to 1905, and had served as president to all the Glasgow medical societies. He took charge of the Scottish Red Cross Hospital in the South African War, and was made a C.M.G.

DANGERS ASSOCIATED WITH REMOVAL OF THE TONSILS AND ADENOID GROWTHS.

To the Editor of the Medical Record:

Sir:—I have read the article by Dr. F. C. Ard in your issue of March 6 and wish to refute some of his statements and correct one of his quotations, with the hope that I may provoke a discussion of this matter, in which I have been very much interested for some years. Dr. Ard's article states, "The ease with which chloroform is administered." Chloroform is not properly administered with any greater ease than ether, but it is much easier to smother and kill a patient with chloroform than with ether. He says: "Careful investigation proves that many deaths have resulted from its administration." Careful investigation also proves that many deaths have resulted from the administration of ether. He states: "It is now becoming generally recognized that children have the status lymphaticus." I believe that there are cases of status lymphaticus among children and adults, but I am surprised to hear that *all* children suffer from this condition. I have never had any "narrow escapes" in my own practice under the use of pure and fresh chloroform, therefore I do not have to endure "the inconveniences of ether" for myself nor worry about the secondary dangers of its administration to my patients who are nephritic and have a tendency to secondary hemorrhage. He states: "Hemorrhage calling for immediate interference may be immediate, belated, or secondary." Immediate hemorrhage can always be controlled by the same surgical measures that are necessary in other parts of the body. Secondary hemorrhage in the case of adenoids almost always is caused by their incomplete removal; in the case of faucial tonsils for the same reason from the use of the tonsillotome or tonsil punch. I have repeatedly operated for the relief of secondary hemorrhage following incompetent operations in other hands for adenoids, by their complete removal with entire satisfaction. For secondary tonsil hemorrhage, three interrupted sutures coapting the faucial pillars have always been successful in controlling hemorrhage in this situation without the interposition of any gauze pad or other foreign body.

In quoting Dr. Ballenger, Dr. Ard says: "In young children tonsillotomy is not necessarily a hospital operation." I desire to do Dr. Ballenger the justice to correct the quotation. Dr. Ballenger says: "I can refer to a large number of cases in which I did an incomplete operation, or what is known as clipping the tonsils, with a Mathieu or other tonsillotome, which were followed by unfavorable results," etc. It seems, therefore, that the time has come when a textbook should clearly recommend that the complete operation upon tonsils is the one that should be used (*i.e.* tonsillectomy). Later, on page 414 of his work, Dr. Ballenger says: "In young children tonsillectomy is not necessarily a hospital operation, as it is very rarely followed by hemorrhage or sepsis." I have myself administered ether, ethyl chloride, nitrous oxide, and chloroform for this work, and I have had pure and fresh chloroform administered for me in my practice for a sufficient number of years and to a sufficient number of patients to prove to my satisfaction that it is the safest of all anesthetics, when properly administered by a careful and competent anesthetist and under my personal observation. I have also proved to my own satisfaction that tonsillotomy is rarely, if ever, a satisfactory operation, and that tonsillectomy in competent hands is always satisfactory in its immediate results and rarely followed by any disturbances, with regard either to hemorrhage or to sepsis.

Passaic, N. J. Fred. F. C Demarest

Progress of Medical Science.

Boston Medical and Surgical Journal, March 4, 1909.

Some Observations on Renal Diagnosis.—C. H. Chetwood makes some observations on functional kidney tests, noting that a diseased kidney has a more uniform function than a healthy organ, that its function varies less from one time to another the more extensively its parenchyma is destroyed, and that if one kidney is diseased, or is the more diseased of the two, when the urinary function becomes disturbed, it modifies its function less than the other. He discusses the value of the phloridzin and indigo-carmine tests and gives the clinical histories of several cases. He says that it is by judicious selection and combination of the various available tests that the best results are obtained and the most satisfactory preliminary diagnosis accomplished in surgical lesions of the kidneys. All tests need not be resorted to in every case. We should ascertain which organ is diseased and especially the condition of the other organ when a nephrectomy is still possible. Simple cystoscopy may determine the exact location of the lesion and the two tests, named above, accompanied by segregation or catheterization of one ureter, will usually furnish the desired information. If the ureter of the unsuspected kidney appears normal and its secretion also normal in quantity and quality and if the evidence afforded by the above tests is positive there need be no indecision. If the results with cystoscopy are uncertain and the test uncertain with a possibly unfavorable discrimination as regards one kidney, diagnosis is more difficult, and we must resort to all varieties of test before coming to our conclusion. In reaching a decision in obscure cases it should be remembered that a diseased kidney may exert restraint upon the functional capacity of the opposite kidney, especially in the case of phloridzin glycosuria, when by means of other differential tests a sufficiently definite net result must be sought to justify a satisfactory diagnosis preparatory to operation. Inasmuch as the progressive development of cystoscopic and functional diagnosis represents so important an element in urological technique, the skillful routine employment of these means is essential to the supremacy of the genito-urinary surgeon in this field of surgery.

The Principles of Mechanotherapy, with Special Reference to Orthopedic Cases.—C. H. Buelolz considers this question under the headings of prophylaxis, preparatory treatment, as the main treatment, and after-treatment. Mechanotherapy must be considered as an essential factor in the treatment of many orthopedic conditions. The result obtained from it will depend in a great measure on the correct use of the methods and the experience of the surgeon and his assistants. The treatment must be elaborated for each single case according to the anatomical, physiological, and pathological conditions. The most important instrument in mechanotherapy is the hand of the surgeon, but for several conditions apparatus is required. For a hospital with a large out-patient service it is a preeminent advantage to have at hand a medicomechanical department such as Zander's, where the treatment singly or in classes and under expert direction may be carried on in a varied way.

New York Medical Journal, March 6, 1909.

A Clinical Note on Alimentary Albuminuria.—A. C. Croftan has found that the disorders in which this form of albuminuria is most apt to occur are (1) motor insufficiency of the stomach of advanced degree, particularly if combined with secretory depression (hypochlorhydria and hypochylia). In achylia gastrica combined with motor insufficiency, this form of albuminuria is particularly common. (2) In diarrheic disorders of all kinds and particularly in cases of pancreatic debility with accompanying intestinal dystrypsia. (3) In hepatic insufficiency of various origin. (4) After the ingestion of abnormally large quantities of albumin (noted especially in diabetics on a meat-fat diet) and in cases in which large quantities of albuminous food, particularly egg albumen, are injected into the rectum in the form of nutritive clysmata. The treatment consists essentially in the removal of the causative factors. In cases of motor insufficiency with hypochlorhydria or achylia gastrica, the supplying of a sufficient quantity of hydrochloric acid and all measures directed toward overcoming stagnation of stomach contents, as a rule, promptly cause a disappearance of the albumin from the urine. Attention directed toward the correction of intestinal dystrypsia is particularly useful in removing this particular form of albuminuria, and here the administration of large quantities of an alkali with pancreatic extracts frequently leads to the goal. In the case of alimentary albuminuria following rectal feeding with large quantities of eggs, the addition to the nutritive enemata of considerable quantities of alkali and pancreas again generally causes the disappearance of the albumin from the urine. While small amounts of albumin in the urine may not be in themselves dangerous, yet the circulation in the system of foreign or toxic albumin irritates the renal epithelium in the convoluted tubes and so may lead up to kidney disease. It is essential, then, to recognize that there is a form of albuminuria of rather favorable prognosis that is not primarily due to renal debility, nor to nephritis, nor to circulatory disturbances in the kidneys as a part phenomenon of general cardiovascular disease (Bright's disease, arteriosclerosis), but that is enterogenous in type and primarily and exclusively a gastrointestinal and hepatic disorder.

Alcohol: Physiological Action and Therapeutic Indications.—E. R. Zemp presents a parallel exhibit of the respective effects of food and alcohol on the body. Alcohol is not a stimulant in the true sense of the word or a food. It is a useful drug when properly "used," but it has been terribly abused. Its use requires as much intelligence and judgment as does the use of any other drug. It is not an antidote to carbolic acid. It is a source, in proper amounts, of easily assimilated energy and in small quantities it aids certain forms of indigestion. Locally it possesses values often overlooked. The odor of alcohol on the breath is no criterion as to whether the patient is getting too much or not. In the usual manner of administration it does more harm than good, and the subjective symptoms of the patient under the influence of alcohol no more indicate his true condition than do those from morphine. The drinking of whiskey to keep from "catching cold," or to prevent serious results from snake bites, is a delusion and a snare. When sufficient food is lacking, alcohol in small amounts will prevent body waste, by conserving the tissues. The drinking of whiskey in health is a pleasant, but entirely unnecessary and wasteful, form of amusement, while the habit fixing propensity of alcohol should always be kept in mind by those who prescribe it.

Attempt at Conservatism in Abdominal Surgery.—J. W. Kennedy declares that the laboratory worker has no right to dictate to the surgical veteran who has become skilled in physical diagnosis, although there should be no conflict between the two. The student needs to be taught not less in the laboratory but more from personal contact with the patient. Hence the country practitioner is often the best diagnostician. The author says that we are not using the knowledge acquired through the thirty years just closing. The student is being taught that it is dangerous to open the abdomen in acute peritonitis from most any cause, and even ectopic gestation fares well to be placed on the waiting list. Fortunately, the author says, we have not been asked to wait in strangulated hernia. He has been for some years an assistant in the Price clinic in Philadelphia, and bases his ideas on the results there achieved. They are positively opposed to those who counsel delay in appendicular inflammation, pyosalpinx, or ectopic pregnancy. The rule there is first-hour operations and completed toilets at any stage in peritonitis. The selection of cases in the lesions mentioned is beyond human skill. The author says that in many cases of the retrocecal type of appendix inflammation is rupture of an appendix already gangrenous. As to ectopic gestation, he has collected statistics from twenty prominent clinics with a mortality of eight per cent. in two thousand cases. In the Price clinic one patient has died in one hundred and sixty-five operations. These include eight suppurative cases, and the fatal case was one of suppuration of five months' standing. The operation has been done in every case the first hour the patient has been seen regardless of hemorrhage or shock. Attempts at conservatism for incipient cystic conditions of the ovaries or unilateral removal of uterine appendages for infectious conditions certainly has been anything but brilliant. Some few patients have conceived after conservative work on the uterine appendages, but if one will review his work in those cases where he has made some attempt to save ovaries and tube, and considers the morbidity of such patients, and the very great number who return for second or third operations, he will find that his effort has been a miserable failure. At the Price clinic it is felt that one is never justified in removing one pus tube and permitting the supposed good side to remain. The primary source of infection remains, the remaining tube and ovary are probably already infected, and the patient will return for a second operation at an early date.

Journal of the American Medical Association, March 6, 1909.

Laboratory and Bedside Diagnosis.—W. W. Grant thinks that the criticism of a British observer, Dr. Roleston, that there is too much dependence on laboratory diagnosis in this country and too little on bedside observation and experience, is a just one to a certain extent. There is too much reliance, he says, even when not necessarily exclusive, on instruments of scientific precision and laboratory diagnoses, and too little on the training and discipline of one's own faculties in one's accustomed work. The result is a few expert diagnosticians in certain departments and a general decadence in diagnostic skill and acumen. With our better facilities for teaching and improved advantages generally we ought to have more instead of fewer diagnosticians. The surgeon has magnified aseptic and operative technique, leaving the rest largely to the laboratory, and Grant cites several instances in which exploratory operations and laboratory methods were called in to the patient's disadvantage. In some diseases when a fine differentiation is made, the knowledge of the internist is as essential as the skill of the surgeon or the laboratory expert and the results obtained by instruments of scientific precision are not always accurate and reliable. so much depends on the "man behind the gun." Grant disclaims any intention to depreciate laboratory methods, but he wishes to have clinical expertness better appreciated.

Vaccine Treatment of Erysipelas.—The results of the use of a vaccine prepared from Fehleisen's *Streptococcus erysipelatos* are reported and discussed by G. W. Ross and W. J. Johnson. They employed the vaccine in fifty cases, and from this experience they firmly believe that when properly administered it exercises a specific and controlling influence on the course of the disease—preventing its spread, lessening its severity, and hastening recovery. In the first sixteen cases they followed the method of opsonic therapy, but the results were so satisfactory that in the remainder they felt justified in omitting the usual opsonic blood examinations and had equal success in the remaining cases, many of which were severe. They admit, however, that in certain severe cases the usual thorough blood examination may be required. It is unnecessary, they say, to prepare a vaccine for each case, but it is advisable to have a composite stock of vaccine from several different strains and as many different cases and it is probable they think that the more virulent the case of erysipelas the more valuable will its streptococcus be as a vaccine. Their method has been in almost every case to inoculate with 10,000,000 dead streptococci on the first visit if the case is a severe one and with 20,000,000 if the case is less severe. On the second, in a severe case the patient gets 10,000,000 if there be signs of improvement. The most important of these signs is a certain clearing of the intellect and the next are the lessened tenderness and pain. The temperature is not so valuable, though a fall of two or three degrees on the morning following the injection is a valuable indication for a second inoculation. If, however, no evidence of improvement follows in the severe case and it is impossible to determine the opsonic power of the blood, then 5,000,000 only should be given on the second day. In less severe cases improvement is almost always manifest on the day after inoculation and the patient should receive but half the first dose; that is, 10,000,000.

They then inoculate with 5,000,000, 10,000,000, or 20,000,000 of streptococci on every second day until a week after temperature has reached normal and the erythema has subsided. They are guided as to the dose in each case (when opsonic investigations are impossible or unnecessary) by its severity and the unsatisfactory results as shown by clinical observation. The rule is "The more severe the case and the less satisfactory the clinical response the smaller the dose." The site of inoculation has always been chosen away from the involved area. They have been so successful they have not felt it necessary to attempt inoculation near the site of infection. Nineteen cases observed by them in 1907 which were treated in the ordinary way are tabulated and compared with an equal number treated in 1908 by inoculation and the advantages of the later method in the way of shortening the duration of the disease, avoidance of complication, etc., are very manifest.

Blood Staining Methods.—The chemistry of the methyl alcohol stains for blood is discussed by A. R. Peebles and W. P. Harlow, in an article the conclusions of which are substantially as follows: The changes seen in old methylene blue and eosin staining mixtures are due to a change in the reaction of the methyl alcohol. A too acid staining fluid will stain too red. The neutrophilic granules of the polymorphonuclear leucocytes and the nuclei do not stain well. A too alkaline staining fluid will stain blue, the nuclear elements stain well and sometimes also the neurophilic granules, but the red cells do not color properly. All staining fluids made up with methyl alcohol should be kept in clean dark bottles and kept tightly corked. A good cork is better than a glass stopper, and a bottle that has been coated with asphaltum paint is best. If it has been thoroughly steamed and dried out before using much of the difficulty can be avoided. By titrating with potassium hydrate or glacial acetic acid in methyl alcohol the stain can be brought up to the desired standard or reaction at any time, for any blood. No water should be used in the procedure, as it insures the instability of the stain. This procedure works equally well with Wright's, Hastings', or Harlow's stains, but in working the latter change the reaction of the methylene blue only. Use the neutrophilic granules as the criterion in judging the stained smear. If these do not stain well something is wrong with the staining solution or the technique.

The Lancet, February 27, 1909.

Addisonism as a Family Disease.—D. H. Croom comments on the rarity of this affection in children, and gives the histories of three children in the same family, aged nine, six, and three and one-half years respectively. The series presented, in addition to relationship and age, the feature of a common low blood pressure. Case 1 presented pigmentary changes, asthenic and prostration, and low blood pressure, while in Cases 2 and 3 the pigmentary changes were not so marked, but the pressure was low. The author suggests that in Case 1 both cortex and medulla of the adrenals were affected, while in the other two cases the medulla was primarily affected and the cortex only slightly so, thus supporting the theory previously advanced by Gibson. He adds that it would be interesting to know in which part of the adrenals the lesion begins in Addison's disease, and whether the course of the symptoms is affected according to the initial location of the lesion. Postmortem information shows disease of the whole gland, and consequently we have no definite information on the point indicated. Further studies on blood pressure states in the disease may lead to a further differentiation of types of the malady.

Pancreatic Secretion in the Treatment of Diabetes. After a discussion of the physiology of the carbohydrates and of the pathology of the malady named, W. M. Crofton gives the history of a girl of thirteen years whose symptoms had existed three months, ravenous hunger and a daily excretion of 15 pints of urine being the most prominent features. No alteration was made in the diet, but the child was given four capsules daily of holadin, with a marked diminution of daily urinary excretion. After some seven months one grain of secretion was added daily after meals, but it caused, after a few days of apparent success in diminishing the quantity of urine and sugar output, sore throat and epigastric pain, and was stopped, the holadin being continued. A second addition of secretin was followed by the same sequel. The child was for awhile given more potatoes and less bread, but no change was caused thereby in the urinary conditions. A notable fact for which the author cannot account was that, although less urine was excreted, the sugar percentage remained the same under the holadin, but fell when the additional secretin was given. At the time the case was deported the patient had gained greatly in weight, and was in excellent condition.

A Case of Hepatic Abscess Treated by a Vaccine; Recovery.—The patient of J. H. E. Brock was a man of 37 years. The three specially interesting features of the case were as follows: (1) The position of the abscess. It had burst into the right lung two months before the patient was seen by the author. It may have been a post-dysenteric tropical abscess far back in the right lobe, or may have been a direct result of a preceding appendicitis and sub-diaphragmatic. (2) The existing cause. No liver cells or bile appeared in the expectoration, and the lung did not appear to suffer from the passage of the pus through it. Nor did the sputum show the ameba coli or the tubercle bacillus. The cause appeared to be a special streptococcus which doubtless began the appendix trouble and was responsible for the sequelæ. (3) The treatment. The vaccine in appropriate doses, made from the sputum was injected into the patient's flank after examination of the opsonic index of the blood to the particular streptococcus inoculated. The patient recovered, the liver being dragged upward by the shrinkage of the abscess cavity.

"Starvation Cure" in a Case of Diabetes Mellitus.—F. C. Doble records the case of a man of 56 years, a sufferer for a long time, and with constant glycosuria. He had had a cerebral hemorrhage a year before, one sequel of which was a delusion that he and his family were in a state of poverty and that his wife and children were starving. Although he was very hungry he absolutely refused all food, and only enough milk, beef tea, and eggs could be fed to him, forcibly, to keep him alive. After three months of this diet he began to eat one average meal a day, the forcible feeding being continued. He lost in three months 84 pounds, but every symptom of diabetes disappeared, and when the case was reported the patient had recovered 21 pounds of the lost weight on two meals daily, one of meat and green vegetables and the other of milk and eggs. Except for potatoes and bread, his range of diet was unlimited.

British Medical Journal, February 27, 1909.

The Extirpation of Cancer with Formalin.—T. H. Moorhead gives his experience with this remedy in the case of an elderly woman with a small scirrhus of the right breast. Conditions were favorable for an immediate operation, and this was urged, but refused. When the woman was seen nine months later there was a large sloughing mass with a profuse hemorrhage from the apex. The author plugged the hole with wool dipped in equal parts of formalin and water. When the plug was removed several days later there was a large area quite dry and of cheesy consistency. This was cut away until red showed in the black mass, and the plugging was renewed. This procedure was continued ten weeks without pain, and finally a free, clean granulating surface was left, free from any disease. Unfortunately, the patient died of internal metastasis. The author criticises his course to the extent of saying that the caustic action was carried too deep over the center of the tumor, so that the ribs were exposed. There were some enlarged axillary glands, but the formalin they shrunk until they could no longer be felt. He says that the difficulties in limiting the destructive action of the formalin are too great to make the method one of general application.

On Sleep and Want of Sleep.—R. Farquharson refers to the habits in regard to sleep of some famous men, and discusses some of the causes of insomnia. One of these is an overtaxed brain. Some people can sleep after hot drinks, some after smoking a pipe, some after taking easily digested food after they are in bed. The temperature of the room should be regulated, the bed properly placed, and bed-warming devices employed. Heavy suppers and especially champagne should be avoided. Noises should be suppressed. The author has never seen any one who would acknowledge benefit from such popular devices as counting up to a certain number, etc. In many instances narcotics are necessary. They are often avoided by some physicians who fear habit formation, but, as Brunton once said, "insomnia is a bad habit, and may become permanent if we do not break it." Idiosyncrasies must be borne in mind in prescribing this class of remedies. The author says that morphine is the best remedy, being not hypnotic, but also a good tonic and heart stimulant. Chloral must be used with caution. A series of cases has been recorded in which symptoms arose akin to sepsis with purpuric and scorbutic eruptions, ending fatally. Sleep is produced by brain anemia, and therefore the circulatory disturbance produced by arteriosclerosis, pregnancy, alcoholism, Bright's, glycosuria, all modify the effects of sleep producing remedies.

Arterial Blood Pressure Records Before and After Muscular Exercise.—O. K. Williamson has made a se-

ries of observations on some of the participants in the recent Marathon races, and presents his results in tabulated form. His results point to a rise of from 20 to 40 mm. Hg., corresponding to a height perhaps of 160 to 170 mm. as the measurement which is probably near the limit of reserve power of the normal heart. Consequently these observations throw at least doubt upon the idea that readings obtained in the neighborhood of 300 mm. really represent true blood pressure.

The Treatment of Chronic Gonorrhea by Antigonococcal Vaccines.—Clinical histories of three cases are given by A. Loxton, who believes that this method of treatment will prove of marked service. The gonococcus should be demonstrated in the discharge, the patient's general health brought to the best possible condition before beginning the treatment, and the dosage carried out systematically. He begins with forty or fifty millions of sterile gonococci. Appropriate dosage gives rise only to slight headache and malaise some hours after injections. The latter should be made preferably late in the afternoon.

Münchener medizinische Wochenschrift, February 23, 1909.

Clinical Test for Occult Blood in Feces.—Messerschmidt says that the usual guaiac test for occult blood is frequently negative in cases in which blood is surely present. He has therefore studied the various other reactions proposed for the examination of feces and has decided that the so-called benzidin test is the most trustworthy when modified according to his method. The technique is as follows: A little benzidin is dissolved in two c.c. of glacial acetic acid, fresh solution being made for each test. A small portion of the stool is rubbed up in two c.c. of water, to which a few drops of glacial acetic acid have been added. To three drops of this second solution there are added one to one and a half c.c. of three per cent. watery solution of hydrogen peroxide. Then one or two c.c. of the above benzidin solution is added to the mixture and the whole gently shaken. The presence of blood or of blood derivatives is shown by the appearance of a coloration which differs from green to dark blue, the reaction occurring within a few seconds after the addition of the benzidin solution. The author thinks that in this modification the benzidin test seems to be a positive test for the smallest traces of occult blood in the feces or any other mixture.

Ectopic Pregnancy.—Weisswange says that the mortality of extrauterine pregnanscy can be much diminished if more care is taken in diagnosing the affection and if operation is undertaken as soon as possible at the home of the patient so that the delay and the danger of transporting her are avoided. The ovum in extrauterine pregnancy acts as a destructive neoplasm. The causes of the failure of ovum to reach the uterus must be sought in the changes produced in the tubal mucosa by preceding inflammations; the presence of scar tissue or the mere loss of ciliated epithelium is enough to interfere with the progress of the ovum. Usually ectopic pregnancies end in the first two months of their existence, and only seldom further development of the embryo takes place. Three possibilities exist in this connection: the ovum may die and be absorbed, the tube may rupture, or the ovum may be separated from the mucosa and escape the general peritoneal cavity through the open end of the tube. It is clear that early diagnosis of such pregnancy is as important as early recognition of uterine cancer. The physician must always keep in mind the possibility of ectopic pregnancy in all women, and must obtain a full history of the sexual life of the patient, if possible. History of gonorrhea, of complete or temporary sterility, the history of frequent pain over the tubes and ovaries are important in showing the presence of conditions predisposing to ectopic pregnancy. Sudden, sharp, colicky pain is the important direct symptom of extrauterine pregnancy; it may appear in attacks and may be accompanied by marked tenderness on pressure and rigidity of the overlying muscles. Irregularity of menstruation when other causes are excluded must be taken as another important symptom. The temperature usually remains normal. There may appear the early signs and symptoms of pregnancy, but they are seldom as prominent as in uterine gestation. The most important sign of ectopic pregnancy is the presence of a palpable tumor, accompanying the above indefinite symptoms; vaginal examinations as well as external palpation must be executed very gently, so as not to rupture the sac. The prognosis of extrauterine is always uncertain, but it has been very much bettered lately by the readiness of physicians to operate or advise operation without delay. The only therapy consists in such operative removal of the pregnancy sac, for the growing ovum must be regarded as a malignant neoplasm under these circumstances. The operation of choice should be a laparotomy, with removal of the tube of one side. The prophylaxis should consist in the avoidance of all causes of inflammation of the uterine adnexa, and especially of the most frequent cause, namely, gonorrhea.

Deutsche medizinische Wochenschrift, February 18, 1909.

Treatment of Alcoholism.—Weber says that the great progress in our attitude toward alcoholism is shown by the widespread readiness to look upon this condition as a disease that is to be treated by medical measures. Still more important is the recognition of the importance of prophylaxis of alcoholism, which may be carried out among all young individuals, among such as are congenitally predisposed to the habit and among those who are "driven to drink" by extraneous circumstances. Enough of the physiology of alcohol is known nowadays to state positively that the use of alcohol can have only deleterious effect upon a growing organism; it is therefore the duty of the family physician to warn the parents of the danger of giving alcoholic drinks to children of such occasions as parties, birthdays, etc., as the habit may be very easily engendered. There is likewise no valid reason for prescribing various wines as tonics in the anemic conditions of childhood. In general the therapeutic indications for the use of alcohol at any time should be carefully considered so that the slight stimulation it might produce should not be bought at the price of establishing a habit; in this connection the use of alcohol in anemias of young girls, in the period of lactation, etc., is to be limited as much as possible. The treatment of alcoholism must have two ends in view: The habitual drunkard must be trained to become abstinent and to stay so of his own free will, and the physical and psychic injury caused to the organism by the use of alcohol must be repaired as much as possible. There is no question that both these ends may be attained but only if the treatment is carried out in a properly fitted institution. The stage when an institutional treatment becomes necessary is marked by the development of psychic changes in the alcoholic characterized by weakening of the intellectual powers and of the will of the patient. Once in an institution the first step toward curing alcoholism should consist in discontinuing all alcoholic beverages, which can be safely done in most cases if the heart, the kidneys and the mental condition of the patient are continually watched. The consequences of sudden abstinence from alcohol are never as serious as in the case of opium habit, for instance, if the physical condition of the patient is well taken care of in the beginning of treatment. The usual administration of strychnine and atrophine in the beginning of the cure is not necessary and for the most part useless. Even in cases of delirium tremens alcohol may be stopped at once unless there is an accompanying disease with much fever; in the latter case only gradual diminution in the daily amount of alcohol should be attempted. The motor unrest of delirium is best treated by light restraint, the patient being constantly watched; in case the latter is impossible drugs may be used, paraldehyde, veronal and chloroformamid being safer than trional, sulphonal and chloral hydrate. As much water as possible should be given so that the excretions may be freely diluted. To prevent weakness of the heart it is best to avoid as much as possible the narcotic drugs that affect that organ; infusion of digitalis in moderate dosage may be used as a prophylactic of the condition and after it has fully developed. After the delirium stage is passed the real treatment of alcoholism begins and consists simply in accustoming the patient to abstinence, the examples of the physicians and the attendants in the institution as well as its general atmosphere being very powerful factors in this direction. Such abstinence should be enforced for at least three quarters of a year in most cases before the patient may be trusted to abstain from alcohol if allowed to leave the institution. During that time all possible general and special measures should be taken to strengthen the physical condition of the patient and to repair the harm done by the use of alcohol in the past. The patient must be put in such a state of physical strength that he no longer feels the need of a temporary stimulant. The cure of alcoholism is real only if the patient is able to abstain completely from drink; there can be no moderate drinking after excesses for the latter are reneated in such a case very soon after the restraining influences are removed. The discharged patients should be encouraged to join the various temperance societies after their treatment is completed so as to stay under the influence of abstainers as long as possible.

Book Reviews.

Selections from the Writings, Medical and Neurological, of Sir William Broadbent, Bart., K.C.V.O., Commander of the Legion of Honor, M.D., F.R.C.P., F.R.S., D.Sc., Leeds, LL.D., Edinburgh, St. Andrews, and Toronto. Late Physician in Ordinary to His Majesty the King, and to His Royal Highness the Prince of Wales, and Physician Extraordinary to Her Majesty Queen Victoria, etc. Edited by Walter Broadbent, M.D., M.R.C.P. London: Henry Frowde and Hodder & Stoughton, 1908.

This volume of the Oxford Medical Publications contains a judicious gleaning from the writings of one whose literary activity extended over nearly half a century. During this period there were only two years in which Sir William Broadbent did not publish some paper. The bibliography at the end of this volume gives a list of over 200 papers, etc., from the pen of the author; and of this number 45 are here reprinted. In a brief introduction the editor tells us that the papers here presented have been chosen for various reasons, some for their historic interest, some to illustrate the variety of the author's early work, but most of them for the material of interest which they contain for the medical man of to-day. The selection has been well made, and there is not a paper but has some decided value; many of them are of surpassing interest, and not a few give marked evidence of the sound learning and wide clinical experience of their distinguished author. Among the more recent of the papers are those on: The Conduct of the Heart in the Face of Difficulties; Sleeplessness; Pneumonia; Renal Disease and the Circulation; Epilepsy; Interlobar Empyema; Clinical Significance and Therapeutic Indications of Variations of the Blood Pressure; The Examination of the Heart, and Remarks on Some Affections of Speech. Physicians would do well to read these contributions and to think over them. The volume should have an extensive circulation.

On Infantilism from Chronic Intestinal Infection. Characterized by the Overgrowth and Persistence of Flora of the Nursling Period. A Study of the Clinical Course, Bacteriology, Chemistry, and Therapeutics of Arrested Development in Infancy. By C. A. Herter, M.D., Professor of Pharmacology and Therapeutics, Columbia University. New York: The Macmillan Company, 1908.

This little book gives the results of several years' study by the author in conjunction with Dr. Holt with reference to the causes and management of a hitherto unexplained arrest in the development of children. The evidence rests on a very complete investigation of five frank cases and an equal number of incomplete ones. An enormous amount of work on this complex bacteriological question which necessitated many months' study of the individual cases has brought forth explanations and solutions heretofore not in possession of the profession.

The author gives a complete picture of the clinical signs of this affection, with its strong tendency toward arrest of growth of the physical but not mental attributes of the child, the anemia, exhaustion, and abdominal symptoms. He then considers the bacteria as causative factors and such evidence as the urine may afford in sustaining the diagnosis. He describes the predisposing infections, the sequels and outcome which are apt to follow. The sections on treatment are extremely valuable, although a speedy relief and rapid cure are not as yet obtainable. In fact, a reestablishment of perfect growth and physical development in a well defined case is not to be expected. A perfect mental condition is, however, the usual result even in these cases.

American Practice of Surgery. A Complete System by Representative Surgeons of the United States and Canada. Edited by Joseph Decatur Bryant, M.D., and Albert Henry Buck, M.D. To be published in Eight Royal Octavo Volumes. Volume V., 973 pages, illustrated by 452 line and half-tone engravings in the text and by eight full-page plates by chromolithography and other processes. New York: Wm. Wood & Co., 1908.

With volume V. the second half of this now well-known surgical treatise begins, and with it the work enters into the domain of regional surgery. The first chapter, a very comprehensive one of 378 pages, is on the "Surgical Affections and Wounds of the Head," by Dr. Edward Archibald of Montreal. This is followed by a chapter on the "Surgery of the Cranial Nerves," by Charles H. Frazier of Philadelphia. The "Surgical Diseases, Certain Abnormities, and Wounds of the Face" is the title of a very concise and well written chapter by Dr. Charles G. B. de Nancrede of Ann Arbor. Dr. James S. Stone of Boston writes of "Hairlip and Cleft Palate," and Dr. George C. Harlan of Philadelphia of "Diseases and Wounds of the Eye," including the eyelids. Dr. Robert Lewis, Jr., of New York contributes a very complete chapter on "Surgical Diseases and Wounds of the Ear," supplemented by articles on "Sinus Thrombosis of Otitic Origin; and Suppurative Diseases of the Labyrinth" from the pen of Dr John D. Richards of New York, and on "Pyogenic Diseases of the Brain of Otitic Origin" by Dr. Henry Ottridge of Baltimore, Md. These complete the diseases and injuries of the head. The "Surgical Diseases and Wounds of the Pharynx" receive very adequate treatment by Dr. Charles H. Knight of New York, and Dr. James E. Newcomb of New York writes lucidly on the "Surgical Diseases and Wounds of the Larynx and Trachea," while the volume closes with a short chapter on "Laryngectomy," by Dr Frank Hartley of New York.

This is perhaps the best of the volumes of the series that has yet appeared, at least it is one of the most interesting, dealing as it does with practical subjects which meet the surgeon in his daily work. The chapters on mastoid diseases and brain abscesses of otitic origin are especially timely, these affections being just now a favorite topic of discussion at joint meetings of neurologists and otologists. The standard of excellence established in the first volume of this system of surgery has been well maintained thus far, and in none of the volumes is it higher than in this.

Mental Deficiency (Amentia). By A. F. Tredgold, L.R.C.P. Lond., M.R.C.S. Eng.; Consulting Physician to the National Association for the Feeble-Minded, and to the Littleton Home for Defective Children; Medical Expert to the Royal Commission on the Feeble-Minded; Formerly Research Scholar in Insanity and Neuropathology of the London County Council and Assistant in the Claybury Pathological Laboratory; Late Resident Clinical Assistant in the Northumberland County Asylum, etc. New York: William Wood & Company, 1908.

Since the classic work of the Elder Séguin, on Idiocy, there has been almost a dearth of scientific writings on the subject, excepting those of Bourneville. This is probably on account of the apparently hopeless outlook for treatment which cases of mental defect seem to present Yet this very fact should stimulate scientific research along these lines; and it is gratifying to note that the present work is a laudable effort in the right direction. The book contains a number of tables, charts and excellent illustrations, and presents an attractive appearance. The descriptions are clear and drawn from observations of many cases. The subject of mental deficiency is being brought more and more to public attention by philanthropists, educators, and social writers, as well as by medical men, so that the need for correct diagnosis, treatment, and training of these children, and their proper certification as to fitness for the ungraded classes in the schools, or for special schools, or for training in homes, or asylums, etc. is a question of considerable importance. The author gives an account of the incidence, causation, pathology, mental and physical characteristics, social relationship, diagnosis, prognosis, and treatment of persons suffering from mental deficiency. We do not like the term "amentia," as employed by the author, to include all grades of idiocy, imbecility, and feeble-mindedness. In this country we seldom use the word, and when we do, we restrict it to include only the lowest types of idiocy.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia. Assisted by H. R. M. Landis, M.D., Assistant Physician in the Out-Patient Medical Department of the Jefferson Medical College Hospital. Philadelphia and New York: Lea & Febiger, December 1, 1908.

The current number of Progressive Medicine is on the same lines as heretofore. It contains contributions on Diseases of the digestive tract and allied organs, the liver and pancreas, by D. L. Edsall; Diseases of the kidneys, by J. R. Bradford; Surgery of the extremities, tumors, surgery of joints, shock, anesthesia and infections, by J. C. Bloodgood; Genitourinary diseases, by W. T. Belfield; and Practical therapeutic referendum, by H. R. M. Landis. We would draw special attention to Bloodgood's article, which is particularly valuable; Landis' paper contains a timely *résumé* of psychotherapy; and the whole number is a strong one.

Life Insurance and General Practice. By E. M. Brockbank, M.D. (Vict.), F.R.C.P.; Honorary Assistant Physician, Royal Infirmary, Manchester; Lecturer in Materia Medica and Therapeutics, Victoria University of Manchester. London: Henry Frowde, Hodder and Staughton, 1908.

The first part of this work considers in some detail the routine of making medical examinations for life insurance. It is well written, and contains much that will be of value to medical examiners; at the same time it is not to be confounded with books bearing a similar title which are really nothing more than works on general or physical diagnosis. The second part bears the general heading "Impaired Lives," and contains chapters on: Heredity; height and weight; tuberculosis; gout, arthritis deformans, and chronic rheumatism; syphilis; alcohol; insanity, suicide, and epilepsy; malignant disease; female lives; skin; respiratory system; cardiovascular disease; blood; alimentary system; hernia; urinary organs; albuminuria; diabetes mellitus and glycosuria; nervous system; ear; deformities and abnormalities; thyroid gland; sea and war risks; and tropics. The volume as a whole contains a considerable amount of information, much of it of real worth; and the book will undoubtedly be found useful by all who are called upon to make examinations for life insurance companies.

The Rat Problem. By W. R. Boelter. London: John Bale, Sons & Danielson, 1909.

This little work contains much that is of interest, as well to the intelligent layman as to the physician. It begins with a chapter on the natural history of the rat, with an account of the invasion by the "brown" or "Norwegian" rat of all parts of the civilized world. The second chapter treats of the economic loss caused by rats, dating back to 3,000 years ago in Egypt. It is stated that the annual loss in Great Britain traceable to rats is at least $40,000,000 (£15,000,000). Chapter three deals with the rat in the dissemination of disease. Chapter four is on the means for the extermination of rats. Chapter five is a summary or conclusion, and strongly advocates the passage of a rat law similar to that in force for some years past in Denmark. An appendix gives the rat laws of several colonies and states which have adopted such, followed by a three-page bibliography of works referring to the rat. The book is excellently illustrated.

The National Standard Dispensatory. Containing the National History, Chemistry, Pharmacy, Actions and Uses of Medicines, including those recognized in the Pharmacopœias of the United States, Great Britain, and Germany, with many references to other foreign pharmacopœias. In accordance with the Eighth Decennial Revision of the U. S. Pharmacopœia, by authorization of the Convention. By Hobart Amory Hare, B.Sc., M.D., Professor of Therapeutics and Materia Medica in Jefferson Medical College, Philadelphia; Charles Caspari, Jr., Ph.G., Phar.D., Professor of Theoretical and Applied Pharmacy in the Maryland College of Pharmacy, Baltimore; and Henry H. Rusby, M.D., Professor of Botany and Materia Medica in the College of Pharmacy of the City of New York; Expert in Drug Products, Bureau of Chemistry, Department of Agriculture, Washington, D. C.; Member of the Committee of Revision of the U. S. P.; Joseph F. Geisler Ph.C., Chemist, New York State Department of Agriculture; Edward Kremers, Ph.D., Professor of Chemistry, University of Wisconsin; Daniel Base, Ph.D., Professor of Inorganic and Analytical Chemistry, University of Maryland. New (2d) edition, thoroughly revised. Magnificent imperial octavo, 2,050 pages, with 478 engravings. Philadelphia and New York: Lea & Febiger, 1909.

The plan of this work is to give under each article (noting first whether or not it is contained in the U. S. and British Pharmacopœias, one or both) the synonyms and the equivalents in French and German, and sometimes Italian, Spanish, and Portuguese. Then follow the chemical description, the origin and preparation of the drug, its properties and the tests of its purity, substitutes, pharmaceutical preparations, and a section on its action and uses with its dose expressed in values of the apothecaries' and metric systems. Finally follows a section on special preparations of the substance under discussion and on allied drugs. Of the value of a dispensatory to everyone who has to do with drugs, whether physician or pharmacist, there can be no question; it takes the place of, and supplements, the Pharmacopœia and the National Formulary as well as, to a great extent, many of the treatises on materia medica. The new edition of this work contains a great deal of new matter (200 new articles, the preface states), as well as much that has been revised. A very useful addition is the text of the Pure Food and Drugs Act and Regulations. There are also abstracts of the National Formulary preparations and a number of unofficial formulas, including those dropped from the U. S. Pharmacopœia in the decennial revisions of 1890 and 1900. There are two large and apparently very complete indexes—one general index, with the names of the drugs entered under their Latin and English names, as well as, in many instances, the French, German, Italian, Spanish, and sometimes Portuguese equivalents; the other is a therapeutic index.

Pathogenic Microorganisms, Including Bacteria and Protozoa. A Periodical Manual for Students, Physicians, and Health Officers. By William Hallock Park, M.D., Professor of Bacteriology and Hygiene, University and Bellevue Hospital Medical College, and Director of the Research Laboratory of the Department of Health, New York City; Assisted by Anna W. Williams, M.D., Assistant Director of the Research Laboratory; Pathologist to the New York Infirmary for Women and Children. Third edition, enlarged and thoroughly revised, with 176 engravings and 5 full-page plates. New York and Philadelphia: Lea & Febiger, 1908.

We find in this edition a number of changes and additions, necessitated by the rapid progress in microparasitology made during the three years which have passed since the second edition was issued. Thus the book contains 90 more pages than its predecessor, 50 of which are taken up by the increase in the section on protozoa. Several subjects which in the former edition were treated of in the appendix, either because they were new or because they were not deemed of great importance, have now been transformd to the body of the work and discussed at considerable length; among these are "aggressins," "ultramicroscopic examinations," and the relation of *Stegomyia* to yellow fever. The opsonic theory is fully discussed, in general with approbation, though Park does not regard the opsonic index as a very trustworthy guide on account of the extreme variation in the findings by different observers and at different determinations. A brief but useful glossary of some of the newest technical terms has been added. All these changes and additions are in the line of improvement and help to keep for the work the place which it took on its first appearance among the best of the books on pathogenic microparasitology.

Applied Physiology. A Handbook for Students of Medicine. By Robert Hutchison, M.D., F.R.C.P., Physician to the London Hospital; Assistant Physician to the Hospital for Sick Children, Great Ormond Street; Late Chemical Assistant to the Professor of Physiology, University of Edinburgh, and Demonstrator of Physiology, London Hospital Medical College. Author of "Food and the Principles of Dietetics," "Lectures on Diseases of Children"; joint author of "Clinical Methods," and joint editor of "An Index of Treatment." New York: Longmans, Green & Co.; London: Edward Arnold, 1908.

This is a book of an unusual type. In the first place it is an attempt to apply a knowledge of the facts of physiology to the study of medicine in the same way as anatomy has been applied to the study of surgery. Further, it is the first book of this kind that we have seen. Since it is not intended as a substitute for text-books of physiology, but as a companion and supplement to them, only the *facts* of physiology are dealt with; hence the book is not a large one. The author treats the subject in eight chapters, dealing respectively with the applied physiology of: Metabolism, body heat, the blood and blood-making organs, the heart, the circulation, the respiration, digestion, and excretion. It will be noted that there is nothing on the muscular or nervous systems, or on the special senses; the author being convinced "that most of the nerve muscle physiology as ordinarily taught to students, is perfectly useless to the physician, and as regards the nervous system and special senses, the time is not yet ripe for writing their applied physiology—clinically, one can as yet hardly make use of more than their applied anatomy." The book is written in Dr. Hutchison's well known lucid style; and each chapter contains a valuable application of present-day physiological knowledge to the needs of the clinician. With its absence of theory and descriptions of methods, this is just the book for the practitioner; and its size and typography make it easy to hold and pleasant to read.

A Common-Sense View of the Mind-Cure. By Laura M. Westall. New York and London: Funk & Wagnalls Company, 1908.

This is a primer-like book, written by a layman for lay readers. It is intended to explain the workings of the "will power" in the treatment of the common functional disorders. It is lacking in scientific application.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Section on Medicine.

Stated Meeting, Held January 19, 1909.

Dr. F. P. Solley in the Chair.

A Case of Leprosy.—Dr. Max G. Schlapp presented a woman who was admitted to the hospital because she had burned herself. She said she felt no pain. There were disturbances in the temperature, pain, and tactile senses. He jumped at the conclusion that this was a case of syringomyelia. While entering more fully into her history she called attention to the fact that she had had a spot on her leg which had existed for a long time. He found five on the left leg and one on the right. Her mother was alive and well, and had separated from her father. The patient had not seen her father since she was two years old. The father went to London and she learned from her sister that he had died there of leprosy. The father had leprosy for a long time. She had two brothers who were perfectly well. When she was ten years old she noticed a spot on her leg about the size of a dime. When bathing she noticed that the spot was lighter in color than the rest of her skin. This spot soon reached the diameter of three or four inches, and this was five years ago. Four years ago other spots appeared on her leg. Since 1904 she had noticed areas of analgesia. One and a half years ago she burned herself and immediately after her finger swelled and had remained swollen. Besides the skin lesion, she was hypersensitive all over her body. The tendon reflexes were exaggerated and the plantar reflex was present. There was practically nothing else present except the spots on the skin and the hypersensitive condition of the whole of the body. Unless care was used he thought one might make a diagnosis of syringomyelia, as he did when he first saw the patient.

Two Cases of Leprosy.—Dr. E. B. Bronson presented these cases:

Case I. The patient was a Russian sailor, twenty-six years old. His family history was negative. He had no knowledge of any exposure to leprosy. As a sailor, however, he had spent time in the ports of Norway, Sweden, and Spain. Between two and three years ago he first noticed some little dark spots with elevations on the legs which slowly increased in size and number. About one year later similar spots appeared on the arms. These were slightly elevated, but after a time would become flat and leave only a dusky stain of the skin. There were no constitutional disturbances. The appetite was good and there was no loss of weight. There was some anesthesia of the legs and arms. Alopecia of the eyebrows was present.

Case II. This patient was a male, thirty-three years old, born in California. From his early childhood until he was sixteen years of age he lived in the West Indies. Neither of his parents nor any of his relatives were ever leprous. Since the age of sixteen he had lived in New York. The first symptoms of the disease were noticed about fourteen years ago in the form of discolored lesions on the legs. A few years later there appeared nodules or tubercles in and about the mouth and also on the ears. For the past six years he had been conscious of the loss of tactile sense, as well as numbness in various parts of the body. When he first entered the City Hospital in 1905, the following symptoms were noted: There were elevated nodules on the chin and ears of a pinkish yellow color and soft to the touch. The forehead was comparatively free from these, but the eyelashes and eyebrows were absent. In the roof of the mouth was a large white scar. At a subsequent examination a year or so later, well marked tubercles were found on the epiglottis, arytenoids, and vocal cords. Corneal ulcers with opacities were present, and there were signs of an old iritis in both eyes. The pupils were irregular, with posterior synechias. There was photophobia without especial pain. There was also a perforation of the nasal septum. At his admission to the hospital the legs showed numerous more or less discolored cicatrices. Beneath the left foot was a small ulcer. There were ulcerous lesions also affecting the bed of the nail in several of the toes, and also of the fingers. It was noted that the sole of the affected foot was decidedly analgesic. There was an evening rise of temperature. Since the patient had been in the hospital many of the cutaneous lesions had healed, but the perforating ulcer on the ball of the foot had persisted and had slowly increased in depth. Another ulcer had formed beneath the heel of the same foot. The analgesia or anesthesia had gradually extended. The patient occasionally complained of flashes of heat, and more especially between the ankles and the knees on the inside.

Dr. Prince A. Morrow said that where there was absolute loss of the sense of pain, and more or less disturbance of the tactile sense, one would suppose that the nerve was entirely destroyed; but in these cases the nerve was not dead, and it was quite possible with a strong electric current to cause a return of the sensation. In these cases the majority of the doctors were very much puzzled in making their diagnosis. Leprosy was exceedingly benign in its earliest manifestations. He had seen patients with colored spots about the ankles and legs persisting for five, ten, and even fifteen years, with absolutely no other signs of the disease. It was very difficult to make a diagnosis of leprosy before there were disturbances of nerve sensation. In the first patient presented pressure upon the ulnar nerve elicited no pain, and this was characteristic of the disease, that nerve would not transmit sensation. In some cases with complete analgesia of the entire foot, it was possible to pierce it with a knife or needle and the patient not feel it. In tubercular leprosy the anesthesia was only temporary. The tubercles upon the arms and legs of the patient presented by Dr. Bronson were quite characteristic.

Demonstration of the Bacillus and Lesions of Leprosy.—Dr. Charles Norris demonstrated the bacillus and lesions of leprosy under the microscope.

Photographs of Lepers.—Dr. C. N. B. Camac presented some photographs of lepers.

Leprosy in Norway.—Dr. Henry L. Shively said that leprosy in the Scandinavian Peninsula was certainly known to exist in the time of the Vikings and was probably introduced by them on their return from voyages to countries bordering on the Mediterranean, possibly from Egypt and Syria. Possibly the first allusion to leprosy in Scandinavian literature occurs in two ancient books of law, relating to statutes of Norway dating back to the eleventh century. The first mention of hospital care for lepers was contained in the will of King Haakon, which was executed in 1257. In this instrument it was decreed that the St. Catherine Hospital in Bergen should admit only lepers. This was the oldest of existing institutions for the care of lepers in the whole of Europe and was the scene of the early clinical labors of Danielssen and Boeck who, in 1840, began their pioneer studies in the first truly scientific investigation of the disease. They made a census of the leper population in 1845 which showed a total of 1,112 cases. Other institutions were soon opened. Dr. Shively gave the histories of other institutions for the care of lepers in Norway. St. Jörgens possessed great interest for the medical antiquarian, as in its present form it was said to reproduce faithfully the original buildings destroyed in the fire of 1702. The wealth of this institution to-day was estimated to be

least one and a half million kroner, or $400,000. There were now but 32 lepers in St. Jörgens Hospital. Upon the deaths of its present occupants this hospital would be discontinued as a leper hospital. A portion of the endowment fund was now being expended in the campaign against tuberculosis. Pleiestiftelsen, which was founded in 1857, was the largest of the hospitals in Norway for the care of lepers, accommodating 270, but at present containing only 92 cases. The physician in charge, Dr. H. P. Lie, welcomed the visitors from abroad every morning, and they accompanied him through the wards. The cases were in general classified as lepra tuberosa, lepra maculoanesthetica, and lepra tuberosa anesthetica. The greater number were from the peasant classes. One was struck by the number of lepers who attained advanced age. These advanced cases resembled blanched mummies with their white, atrophic, tightly drawn, parchment-like skins, as thin and as translucent as cigarette paper through which the underlying blood vessels, and even the bones, were plainly visible. Fingers and toes frequently underwent spontaneous amputation from necrosis and absorption of the small bones. Twenty-five per cent. of all the cases were blind, and ectropion was a common eye condition with loss of the brows and eyelashes. Tuberculosis was a frequent complication, and nephritis was usually present. Inhalation pneumonia, erysipelas, septicemia, laryngeal stenosis, organic heart disease, and amyloid degeneration of the viscera were the common causes of death. The liver and spleen were usually enlarged. In Norway the nodular was more than twice as frequent as the anesthetic form. Apparently so far as any real or permanent effect upon the disease was concerned, no treatment had been of much value. The difficulty in the treatment of leprosy, as pointed out by Lie, was the failure of reaction of the tissues, a factor that was also present in and made so discouraging the treatment of malignant disease otherwise than by surgery. At St. Jörgens Hospital some of the attendants had lived more than thirty years in intimate contact with lepers and no trace of the disease had appeared in them. From 1857 to 1900, according to the official statistics of Hansen, 307 lepers were known to have emigrated from Norway, and probably with few exceptions had been domiciled in the United States. It was certainly known that 180 lepers, of whom Hansen had definite records, had emigrated to this country. Of this very considerable emigration of lepers practically all had eluded the vigilance of the immigration inspectors. It would appear that the liberal immigration policy of this country had been quite as much a factor in diminishing the leper population of Norway as her measures of segregation and the notable improvement in living conditions which had taken place in that country during the last quarter century. Norwegian leprologists were all contagionists agreeing that the disease required a long and intimate exposure in order to be communicated. Leprosy might be regarded in a sense as the national disease of Norway. Hansen had predicted that the disease would be extinguished in Norway in 1920 if the present rate of decrease continued. To the attainment of this desirable condition for Norway the United States might justly feel that she had contributed in no small degree by the generous reception accorded leper immigrants from that country. The time might come when leprosaria would be established in this country and the unenviable distinction of being a center for the study of leprosy pass from Norway to the United States.

State Cure of Leprosy as It Affects the United States.—Dr. Albert S. Ashmead said that in his investigation of Scandinavian leprosy in the United States 316 lepers, known to the authorities of Norway to be lepers, had been allowed to emigrate to this country and 175,000 leper families, in each of whom one or more lepers had been found, had been shipped as emigrants to America. Many, if not most, of these families carried the latent germs. Facultative isolation was responsible for all this emigration evil of leprosy to the United States. One-half the population of Norway had been permitted to come here while Hansen was being glorified for the gradual eradication of leprosy from his country. And now, in his honor, a second conference on leprosy had been called to meet at Bergen next August. It was of supreme moment to the United States to learn whether this transference of 900,000 Scandinavians to this country had not been the main factor by which Hansen had almost completely conquered the Norwegian evil. Hansen had said, "In 1920 there will be no more lepers in my country." He also had said, "If you seek my monument, look about you." By that time all his lepers would be dead and the suspicious ones transported to the United States. The people of this country, therefore, must study two questions pertaining to leprosy, the contagiousness of the disease and its epidemiology. Leprologists believed, first, that the disease respected neither sex, age, nor social condition, and most naturally affected those individuals of any race who were of delicate organization, or debilitated by wretchedness, privations, excesses, or previous disease; second, that leprosy spread itself in all latitudes and that New York could be no exception to the contagion, no matter what the eminent advisers of the Board of Health foolishly claimed to the contrary, and no matter how prominent and distinguished those dermatologists were in their own specialty, they were not epidemiologists. Leprosy was a science in itself. The one thing that conduced most to the prevalent error about leprosy was that the duration of the latent period was totally undetermined. Leprologists believed that the disease was naturally infectious, either by direct or indirect methods of contact. The theory of heredity had been rejected. The contagiousness of leprosy was greater or less, in accordance with the form by which the disease revealed itself, and the period of its unfolding. The mutilating form was most virulently contagious. There were but three methods known to science to free a country of epidemic leprosy: (1) Destruction of all lepers by death, or their outcasting absolutely from families; (2) obligatory segregation, *i.e.* taking the lepers away from their families; (3) deportation of all lepers. The present situation of matters in this country was as follows: The number of lepers in the United States, of all nationalities, was far in excess of the number, 278, reported by the Marine Hospital Congressional Investigation Committee. Dr. Ashmead estimated the whole number to be really about 3,000. Of this number 400 were Scandinavians. It had been estimated that there were at least 300 Chinese lepers in the United States, most of them employed in washing the linen of Americans and so hidden in the laundries. There had been introduced into Congress four leper bills. The Platt-Wanger Leper Bill provided for a National Leprosarium, to be in the center of Yellowstone Park, 29 miles from the circumference, a site of perfect isolation. The bill was killed in committee. Congress having failed to help the situation, Dr. Ashmead had made an appeal for funds to establish a philanthropic National Leper Asylum, and had suggested that the Adirondacks be selected as its site.

Dr. John A. Fordyce said it had been his pleasure, while traveling through Norway in 1905, to visit the Leper Hospital in Bergen, and through the kindness of Dr. H. P. Lie, who was the medical director of the hospital, to inspect the building and see the patients. At that time Dr. Lie said there were in all Norway about 350 lepers, and that the number of cases was diminishing while tuberculosis was increasing. This was not altogether attributed to segregation, for the patients were permitted to remain at home if quarantine could be enforced there.

but, owing to the poverty of the people, this was more or less imperfect. The manner in which infection took place was no nearer solution here than in other leprous districts, as no initial lesion had been demonstrated and the incubation period was such a long one. In all countries where leprosy was endemic there was much negative evidence on the subject of the infectiousness of the malady, but in the face of occasional positive evidence this negative evidence was not of much value in controverting the theory of infectiousness. In his histological studies, Dr. Lie demonstrated that in the macular lesions of the anæsthetic type the bacilli were first present in the finer cutaneous nerves and then invaded the larger nerve trunks, the organisms rapidly disappearing from the skin lesions. While a secondary implication of the nerves was possible, an ascending neuritis was the usual course of the infection. Dr. Fordyce said cases demonstrating the long duration of the disease were shown him, among them a woman of 74 who had been afflicted for thirty-nine years. The characteristic yellowish conjunctival discoloration of early eye leprosy and other ocular lesions were exhibited, as well as nasal lesions very like lupus vulgaris and serpiginous lesions which simulated syphilis. He also saw an unusual case of unilateral cyanosis and edema of the hand. This condition usually affected both hands, and had been noted by Dr. Fordyce in patients under his observation at the City Hospital. He thought it was probably an angioneurotic condition as a result of the neuritis. In Dr. Fordyce's opinion the diminution in the number of cases of leprosy in Norway was due to the improved hygienic conditions of the people. In speaking of the spontaneous cure of anesthetic leprosy, he said this was not unusual, but as a rule took place after there had been marked trophic and other changes. Mild cases of the anesthetic type had been reported which did not progress beyond a perceptible neuritis and macular lesions in the skin. Abraham had seen such cases from India in which spontaneous cure took place and the patients remained well. This fortunate termination was seldom encountered in the tubercular or nodular variety. At the Sixth International Dermatological Congress Dr. Campana of Rome made an interesting observation regarding the contagiousness of leprosy. He stated that as the bacilli were more easily demonstrable in the initial period of tubercular leprosy than in the advanced stages or during the period of resolution, the disease after it became well-defined ceased to be contagious, the contagion being present only during the developmental stage. This observation, while worthy of attention, was not accepted by leprologists in general. At the City Hospital, where there were always one or more cases of leprosy, Dr. Fordyce said no attempt was made to isolate them and only the usual precautions in connection with the transmission of venereal diseases were taken. No case of contagion had been observed. Owing to the close similarity between the various forms of infectious granulomata it was not surprising that occasional mistakes in diagnosis occurred. Dr. Fordyce showed the photograph of a case in which, on account of the general appearance and distribution of the lesions, a diagnosis of idiopathic multiple hemorrhagic sarcoma had been made. Some of the tissue stained for lepra bacilli, however, demonstrated the organisms in enormous numbers. Confusion might also arise on account of its resemblance to syphilitic lesions, and Dr. Fordyce cited a case from his experience in a South American with a generalized brownish-red eruption. He gave a history of syphilis and an eruption which had disappeared under mixed treatment. The following year he had another generalized eruption for which he was admitted to the hospital. The lesions were described as elevated, hard, and hypersensitive, and as they disappeared under injections of mercury his physician was convinced of their syphilitic nature. When seen by Dr. Fordyce, in addition to the brownish-red eruption the patient exhibited a thickening and sensibility of both ulnar nerves and atrophy of the muscles of the ball of the left thumb. The diagnosis was confirmed by the presence of bacilli in the tissues. White and Richardson of Boston recently reported a case in which a mistaken diagnosis of syphilis was made by some of the most eminent dermatologists who were then visiting the International Dermatological Congress. The patient was a young woman of nineteen years from the Province of Courland. Although a microscopical examination demonstrated the bacilli in the tissues, no one, owing to the unusual clinical features of the case, was willing to accept the diagnosis of leprosy. The influence of intramuscular injections of mercury on the involution of lepromata Dr. Fordyce said had been noted by Crocker and others. Eye lesions were seen in most of the cases at the City Hospital, sometimes as sharply defined nodes at the scleroconjunctival junction followed by complete destruction of the organ. A panophthalmitis was observed a few years ago in a negro from Central America, in whom few other lesions were present aside from destruction of the eye. Dr. Fordyce showed a number of photographs of cases of leprosy which had been under his care, and also photographs sent to him by Dr. Echevarria of Costa Rica and Dr. Alderson of San Francisco, illustrating the nodular and maculoanesthetic types of the disease.

Dr. Prince A. Morrow said that in his opinion there could be no possible question of the contagiousness of leprosy, although it was undoubtedly modified by climatic and other conditions, such as unhygienic surroundings and modes of living. For example, the facts of its development and spread in the Hawaiian Islands furnished conclusive proofs of its marked contagiousness, whereas in the United States observation showed that its contagious activity was materially modified. It was very difficult to speak positively regarding the communication of this disease from one individual to another when the incubation was so prolonged, extending, as it often did, over a period of many years. In the leper settlement of Molokai there had been repeated cases of women who washed the clothes of lepers and remained exempt from any manifestations of the disease for ten, fifteen, or even twenty years, and yet later developed undoubted evidences of leprosy. He might refer to the case of the successor of Father Damien at Molokai who had always lived in the United States and had never been exposed to the contagion until he came to the Leper Settlement, yet when Dr. Morrow examined him three or four years later he discovered unmistakable signs of leprosy. At that time there were no manifestations upon the skin, only implication of the ulnar and other nerves, but other confirmatory evidences were soon presented. For twenty years or more this gentleman has led an active life and accomplished an enormous amount of work, without serious crippling from his disease. In this connection Dr. Morrow would say that there was no other constitutional disease so severe in its later manifestations and so progressively fatal in character which granted its victims so long a lease of active and useful life as anesthetic leprosy. Of interest in relation to the contagiousness of leprosy was the source of the contagion and the port of entry of the bacilli into the system. Dr. Morrow thought that its communicative mode was like that of tuberculosis—that the bacilli gained entrance into the organism through the air passages in the immense majority of cases. While he did not deny that leprosy might be exceptionally conveyed by mosquitos or other insects directly through the integument, there had been furnished no positive evidence of it. His theory of the entry of the germs via the nasal passages, announced nearly twenty years ago, was based upon the observed clinical fact that

changes in the mucous surfaces of the upper air passages were among the most common, and certainly the most precocious symptoms of leprosy. This theory has been confirmed by the bacteriological demonstration of leprous bacilli in the nasal passages in the large proportion of lepers, even before there were active manifestations of the disease elsewhere. When Dr. Morrow visited the Molokai settlement in 1889 he was much interested in the investigation of certain moot points about leprosy—such, for example, as the mode of invasion of the bacilli, the arrest of development of the disease, its spontaneous cure, and the effects of treatment upon the limitation or cure of the disease. He asked the gentlemen in charge of the settlement to make observations upon these points, and his report showed that while the native Hawaiian is not subject to catarrh, every leper has nasal catarrh, that two-thirds of them or more have ulceration or perforation of the septum, that cases of arrest of the disease, continuing for years, are not uncommon, that either with or without treatment there are not a few cases which appear to be cured. Dr. Morrow reported a case of anesthetic leprosy under his care for five years in which the disease had been completely cured, and had remained absolutely free from any and all manifestations for ten years past. He thought that one could not too strongly exphasize the fact of the curability of leprosy. He did not share the views of Dr. Ashmead in his apprehension of an epidemic of leprosy in this country. At any rate, an effective quarantine could not be fully established in this country without the cooperation of other governments. He had seen and had examined over 200 lepers in this city; most of these were the advanced cases. Very little could be done in the exclusion of leprosy from this country by quarantine except through international cooperation.

Dr. Henry W. Berg said that years ago, at the Riverside Hospital, the use of injections of the mixed toxins of the bacillus prodigiosus and that of erysipelas in these cases of leprosy had been tried, but without successful results. It was tried in three cases, and although a marked reaction followed in each case, the disease seemed to progress more rapidly than before. An attempt had been made to found a leprosarium in this city at that time, but the colony had to be abandoned for various reasons.

GENITOURINARY SECTION.

Stated Meeting, January 20, 1909

Dr. Martin W. Ware, Chairman

Nephrectomy for Calculous Pyelonephritis.—Presented by Dr. Charles Goodman. The patient was a boy, nineteen years old, who was referred to the speaker on July 19, 1908, by Dr. M. Rosenthal, with a history of occasional slight pain in the lumbar region. Ten days prior to his admission to the Sydenham Hospital he began to suffer acute pain in the left side; he became prostrated and his bowels could not be moved for about five days. There was no difficulty in micturition, but he had noted at times that his urine was very turbid. There was no venereal history. The blood showed a leucocyte count of 15,400; polynuclears, 79 per cent. The urine contained large quantities of pus. In the left lumbar region, and extending into the abdomen, was a large, semifluctuating mass; this was readily palpated, and seemed to occupy almost the entire abdominal cavity on that side. A radiograph was taken, which proved unsatisfactory. The cystoscope showed comparatively clear fluid coming from the right ureter, while that from the left contained thick, stringy masses of purulent material. On July 20, 1908, Dr. Goodman exposed the left kidney through a lumbar oblique incision, and after incising the upper pole and evacuating a large quantity of fetid purulent urine, he removed a marble-shaped calculus. The lower pole was similarly incised, and a second round calculus removed from a large abscess cavity. The combined quantities of material evacuated from the two cavities measured at least three pints. The kidney seemed almost entirely disintegrated and the indications for its removal were imperative, but on account of the poor condition of the patient, nephrectomy was not done until three weeks later. During the first twenty-four hours after the operation the patient passed twelve ounces of urine; at the end of ten days the quantity had increased to forty ounces. Pathologically, the removed kidney showed a suppurative pyelonephritis, nephrolithiasis being the inciting cause.

Foreign Body Calculus from a Female Bladder.—Dr. Goodman showed the specimen in this case, which was removed from the bladder of a middle-aged widow last November through a suprapubic opening. She had been treated for some time for supposed kidney trouble before consulting Dr. R. Kunitzer, who recognized that there was a foreign body in the bladder. This was confirmed with the Thompson searcher and the cystoscope. On November 30, 1908, the bladder was opened by Dr. Goodman, who did a suprapubic cystotomy, and removed a fragment of a bougie, covered by phosphatic deposits and tipped with an olive-shaped calculus. The bladder, which was completely closed, was drained through the urethra for three days. The patient was out of bed on the sixth day with her wound practically healed, and entirely relieved of the frequency and tenesmus from which she had suffered before the operation. She confessed that eight months prior to that time the bougie had been inserted by a midwife.

Hematuria Following Nephrectomy for Tuberculosis.—Dr. F. Tilden Brown reported two cases. Both of these patients were young people in whom hematuria of a moderate grade developed after the removal of a tuberculous kidney; in one on the sixth day after the operation; in the other, on the tenth day. Dr. Brown said that while he was not able to state positively where the blood originated, he thought it fair to presume that an ulcerative lesion at the mouth of the corresponding ureter was its most probable site, but why such a lesion should take on this form of activity while the patient was at rest in bed, and why it should occur after a nephrectomy in cases where there was no previous history of bleeding, was peculiar. Another theory was that the hemorrhage came from the opposite kidney, either as the result of hyperemia from the extra work thrown upon it, or the possible presence of a tuberculous focus which had hitherto remained dormant, because up to the time of the nephrectomy the urine from the kidney on the opposite side, obtained by ureteral catheterization, had been absolutely free from any abnormal elements. Dr. Brown then gave in detail the history of his two cases.

Dr. Martin W. Ware reported four cases. All of these patients had been shown at previous meetings of the section. One of the cases was that of a girl of fourteen, who gave a protracted history of tuberculosis of one kidney. At the time of the removal of the organ its ureter was found to be much diseased. This delayed her recovery, and a few months after the nephrectomy she developed persistent hematuria. The bladder was opened, revealing an ulceration close to the mouth of the ureter. This was cauterized, and as a result of this the hematuria ceased and the wound in the bladder finally closed. In the second case reported, the hematuria was one of the earliest symptoms of the tuberculosis of the kidney, and it recurred six months after the removal of the affected organ. In the third case the bleeding occurred after the nephrectomy, and a cystoscopic examination showed a large number of engorged blood vessels in the bladder. The fourth case

reported was that of a man, who, after the removal of his tuberculous kidney, had repeated attacks of hematuria. He subsequently developed tuberculosis of the epididymis, with marked induration of the seminal vesicle and cord on the same side, and it was not at all unlikely in this case, Dr. Ware said, that some of the bleeding came from that source.

Dr. H. Goldenberg said that while he had no explanation to offer for the hematuria in the cases reported by Drs. Brown and Ware, it struck him that there was a difference between the two types of cases. In the cases reported by Dr. Brown, the bleeding came on shortly after the operation, while in one of the cases reported by Dr. Ware it came on about one year after the operation, and the cystoscope showed engorgement of the blood-vessels in the bladder. In that case the hemorrhage was possibly due to the rupture of one of these varicosities. The urethra was another possible source of hemorrhage in some of these cases.

Dr. Frederic Bierhoff said that hematuria of renal origin might precede by a number of years the appearance of tubercle bacilli or even pus in the urine, and in at least some of the cases recorded by Drs. Brown and Ware the hemorrhage may have come from an early tuberculous process in the second kidney. The bleeding in these cases was usually the result of the rupture of a small artery or capillary, the walls of which had become eroded by the tuberculous process, and this was the more likely to occur in a kidney, perhaps only slightly diseased, that was suddenly called upon to do double duty.

Excision of a Large Prostate Seven Years After Bottini's Operation.—By Dr. Charles A. Elsberg. The patient was a man of seventy-four, who gave the usual prostatic history and upon whom a Bottini operation had been done seven years before. The prostate was found to be very much enlarged, and the patient's chief symptoms were painful micturition and hematuria. The operation was done in two stages. First, the bladder was opened under cocaine and drained for six days; then the prostatectomy was completed through the suprapubic opening. The removal of the prostate was made somewhat more difficult by the previous Bottini operation. The prostate showed clearly a layer of fibrous tissue on the median side of each lateral lobe where the Bottini cauterization had been done.

Dr. Ware referred to a case in which the prostate was enlarged to such a degree, notwithstanding a Bottini operation seven years ago, that it formed an obstruction in the rectum. In spite of that fact, the patient was able, with some difficulty, to void his urine.

Dr. Benjamin S. Barringer, discussing Dr. Elsberg's case, emphasized the fact that the Bottini operation was not an operation for enlarged prostate, and that it should be limited to special cases of contracted bladder neck, without any enlargement of the prostate. Cases of that type were certainly benefited by the Chetwood modification of Bottini's method.

Dr. Ware said that in one of his cases of hematuria following nephrectomy for renal tuberculosis, with the subsequent development of an acute epididymitis, the patient gave a history of having been mistakenly operated upon for enlarged prostate by the Chetwood galvanocautery method.

A New Catheterizing Cystoscope for Exceptional Bladder Conditions.—Dr. F. Tilden Brown showed this instrument. It was fitted with an indirect vision lens, and the lamp was placed towards the heel of the instrument instead of near the tip, so that the lamp and lens were on the same plane. The instrument was intended for use in certain cases of difficulty due to exceptional bladder conditions and also in certain other cases of prostatic hypertrophy

Philadelphia Neurological Society

At a stated meeting held February 26 Dr. S. D. Ludlum presented a communication entitled "Cardiac Crises in Tabes," and he showed a patient suffering from tabes who complained from time to time of attacks of precordial oppression and pain, with palpitation and rapid action of the heart. The condition is by some considered a vago accessory disorder, but Dr. Ludlum suggested that it may arise from disturbance of the sympathetic nervous system, fibers of which enter the spinal cord in the posterior nerve-roots and make their exit in the anterior roots. Dr. John H. W. Rhein demonstrated "A Possible Case of Landry's Palsy, Presented for Diagnosis." The patient was a barber, who was seized rather abruptly with loss of power in one and then in the other lower extremity, and finally in one upper extremity, with slight tenderness in the calves of the legs, and at first quantitative and later qualitative changes in the electric reactions of the affected muscles, but with increase in the knee-jerks and escape of the sphincters. Improvement set in under treatment. The case was thought to be one of Landry's paralysis, especially on account of the ascending character of the palsy and the absence of pronounced sensory phenomena. In the discussion the opinion was expressed that the case was more probably one of motor peripheral neuritis. Dr Theodore H. Weisenburg presented "A Case of Cerebellar Meningocele." The patient was a child two years old with a characteristic cerebellar gait and with a soft fluctuating mass in the suboccipital region, and pressure on which induced symptoms of intracranial compression. The swelling had been present from birth, which had occurred without abnormality or complication, and the child had learned to walk at an early period, and its intelligence was well developed. The eyegrounds were normal and there was no other motor disturbance. Dr. F. X. Dercum presented "A Case of Poliomyelitis in an Adult Following a Wound in the Hand." The patient was a man, forty-two years old, who, following an infected wound of the right hand, developed weakness and wasting, and fibrillary twitching in the muscles of the upper extremity on the same side, and subsequently on the opposite side also, and likewise of the shoulder girdle. The possibility of the condition having been a peripheral neuritis with extension to the spinal cord was suggested. Dr. Dercum also presented a man whose parents had been deafmutes and who himself had worked in lead, and who presented weakness and wasting in both extremities more pronounced on the left side, and in this likewise a diagnosis of chronic anterior poliomyelitis of the adult was proposed. Dr. S. Weir Mitchell presented a communication entitled "Chorea of Emotion." He detailed the case of a man, forty-five years old, who had exercised his memory considerably and who had been subjected to certain annoyance in the course of his business. From this time on the patient had exhibited marked tremulousness in writing and in performing other motor acts when under observation, or when agitated from any cause. Dr. Mitchell viewed the disorder as a sort of exaggeration of the perturbation manifested by many persons under similar conditions, as when taken by surprise or in undertaking things in the performance of which they feel some uncertainty or incompetency. Dr. Paul H. Bickle read a paper entitled "The Relation of Tabes and Aortic Aneurysm." He reported two cases in which this combination of disorders existed, and he discussed the question as to whether both were the accidental sequels of the same cause, especially syphilis, or whether a more intimate association existed between them. Dr. George F. Price reported "A Case of Meralgia Paraesthetica Recurring with Repeated Pregnancies," and he exhibited "A Case of Myopathy of Unusual Distribution." The latter occurred in a girl about eighteen years old, who presented

atrophy of the muscles of the shoulder girdle, without fibrillary contraction or reactions of degeneration or sensory changes, and a winged position of the scapulæ, more marked on one side. Dr. M. D. Bloomfield reported "A Case of Tuberculoma of the Brain; Diagnosis; Operation; Recovery." The patient was a Russian about thirty-four years old, who had often sustained slight injury of the head and suffered from frequent convulsive seizures, beginning in the right hand and becoming general, with signs of tuberculosis of the lungs and demonstration of tubercle bacilli in the circulating blood. A diagnosis of tuberculoma in the left motor area was made. An osteoplastic flap was resected on the left side of the head, the dura incised, and an infiltrating mass demonstrated in the upper portion of the left ascending frontal convolution. The new growth was in part removed and the wound closed. There was some loss of power in the right upper extremity following the operation, but this gradually improved, and there was no recurrence of the attacks for several months.

Books Received.

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

The Arteries of the Gastro-Intestinal Tract with Inosculation Circle. By Byron Robinson, B.S., M.D., Chicago, Ill. 4to, 222 pages; cloth; illustrated; $1.50. Chicago Medical Book Co., Chicago, Ill.

Mental Deficiency (Amentia). By A. F. Tredgold, L.R.C.P.,Lond., M.R.C.S.,Eng. 8vo, 391 pages; cloth; illustrated; $4.00. William Wood & Co., New York.

A Manual of Natural Therapy. By Thomas D. Luke, M.D., F.R.C.S. (Edin.). 8vo, 303 pages; cloth; illustrated; $2.50. William Wood & Co., New York.

Cataract Extraction. By H. Herbert, F.R.C.S. 8vo, 391 pages; cloth; illustrated; $3.75. William Wood & Co., New York.

Synopsis of Surgery. By Ernest W. Hey Groves, M.S., M.D., B.Sc. (Lond.), F.R.C.S. (Eng.). 12mo, 486 pages; cloth; $2.50. William Wood & Co., New York.

Common Affections of the Liver. By W. Hale White, M.D., F.R.C.P. 12mo, 302 pages; cloth; $2.00. William Wood & Co., New York.

The Bacteriology of the Eye. By Dr. Theodor Axenfeld. Translated by Angus Macnab, B.A., B.Sc., M.B., Ch.B., F.R.C.S. 8vo, 402 pages; cloth; illustrated; $6.00. William Wood & Co., New York.

The Ophthalmic and Cutaneous Diagnosis of Tuberculosis. The Cutaneous and Conjunctival Tuberculosis Reactions, according to v Pirquet and Wolff-Eisner, together with a Discussion of the Clinical Methods for the Early Diagnosis of Pulmonary Tuberculosis. By Dr. Alfred Wolff-Eisner. 8vo, 207 pages; cloth; illustrated; $2.75. William Wood & Co., New York.

Tuberculosis in Infancy and Childhood, Its Pathology, Prevention and Treatment. By various writers. Edited by T. N. Kelynack, M.D. 8vo, 376 pages; cloth; illustrated; $4.00. William Wood & Co.

The Medical Record Visiting List for 1909. 18mo; leather; $1.50. William Wood & Co., New York.

Keen's Surgery. By W. W. Keen, M.D., LL.D. 8vo, 1,194 pages; illustrated; cloth, $7.00; half morocco, $8.00. W. B. Saunders Co., Philadelphia, Pa.

Surgical Memoirs. James G. Mumford, M.D. 8vo, 358 pages; illustrated; cloth. Moffat, Yard & Co., New York City.

Taber's Pocket Encyclopedic Medical Dictionary. Physicians' Edition. By Clarence W. Taber. 16mo, 418 pages; leather, $1.50. Laird & Lee, Chicago, Ill.

Bellevue and Allied Hospitals, City of New York, 6th Annual Report. 8vo, 416 pages; paper; illustrated. Martin B. Brown Press, New York.

Dictionary of Treatment. By Arthur Lathman, M.A., M.D.,Onan., M.A.,Cantab., F.R.C.P.,Lond. 12mo, 325 pages; cloth; $2.00. P. Blakiston's Son & Co., Philadelphia, Pa.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending March 13, 1909:

	Cases	Deaths
Tuberculosis Pulmonalis	485	188
Diphtheria	357	46
Measles	829	22
Scarlet Fever	438	46
Smallpox	1	—
Varicella	246	—
Typhoid Fever	30	6
Whooping Cough	83	6
Cerebrospinal Meningitis	11	9
Malarial Fever	—	—
Totals	2480	323

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending March 12, 1909:

REPORTS OF 300 CASES TREATED WITH A CULTURE OF LACTIC ACID BACTERIA.

BY CHARLES E. NORTH, M.D.,

NEW YORK.

IN a former paper[1] I outlined in general the antagonisms which exist between different forms of bacteria, and particularly between lactic acid bacteria and some of the putrefactive and pathogenic species. I at that time suggested that the theory of Metchnikoff regarding the use of lactic acid bacteria in the intestines[2] as therapeutic agents might be extended to other parts of the body which could be reached by sprays or injections of such cultures. I argued that if lactic acid bacteria were able to antagonize certain species of bacteria which irritated the intestine, they might have the same action wherever they were brought in contact with such bacteria in other body cavities. I suggested the use of cultures of lactic acid bacteria in nose and throat inflammations and as an injection for other body cavities discharging pus.

Following my suggestion, one physician after another became interested in the application of the treatment, until a large group of specialists were engaged in the study and in furnishing me with reports of their results.

Only one species of bacteria and one culture medium has been used in this study. This culture of living bacteria has been used as the agent in the treatment of the cases. Forty physicians have coöperated in the research and over 300 cases have been reported. These include inflammations of the nose, throat, ear, eye, mouth and gums, bones and joints; genitourinary cases, bowel inflammations and surgical cases, including wounds, abscesses, and other inflammations.

History.—There are many interesting facts to be cited regarding the rôle played by lactic acid bacteria in natural economy. There are also many theoretical considerations which have been suggested in the course of our study. I must, however, reserve any discussion of these for another paper and confine myself for the present to the facts connected with this research.

In this country Conn was the pioneer among bacteriologists in the study of the bacteria of milk, and in particular of the lactic acid bacteria found in milk. My studies of these bacteria were begun with Conn in the year 1900. Subsequently I continued these for four years in my own laboratory connected with the production of certified milk, in which business I was for some time engaged. In 1905-6 I made for several months a special study of lactic acid bacteria in the bacteriological laboratory of the College of Physicians and Surgeons, New York, under the direction of Professor Hiss. In this I attempted a classification of these bacteria by means of cultivations in a large variety of sugar media. While this work was never completed, I may say in passing that enough was done to show that a true classification can probably be made through the use of such media. At that time a number of species were isolated and preserved by me because of their special virtue as ferments in producing pleasant tasting sour milk beverages. Later I carried on studies of the various sour milk preparations on the market

I have collected at some pains a complete bibliography of the literature on the subject of lactic acid bacteria and sour milk. This shows the growing use of milk cultures, first in France, later in Germany, America, and other countries, in the treatment of putrefactions of the contents of the intestine. Successful results are reported from the treatment both in adults and in infants and children. Several species of bacteria are recommended by the investigators as ferments for making sour milk beverages intended for use in the treatment of intestinal infections.

Nowhere in the literature, however, have I been able to find any suggestion for the use of milk cultures or other cultures of these bacteria in the treatment of disorders of the nose and throat, or of body cavities other than the intestine. In 1908 my attention was drawn to the putrefactive condition of the nose in atrophic rhinitis. It then occurred to me that sour milk might be injected into the nose to relieve this condition. But the heavy curd in the milk was an objection to its use in this locality. A liquid culture medium free from such curds would obviously be of great advantage. The selection of the proper species of bacteria and of a suitable culture medium was done in connection with studies of these matters which I was conducting at that time.

The Species Selected.—I secured pure cultures of bacteria from a number of buttermilks sold by large milk companies in the city, from all of the preparations of sour milk sold in the drug stores and also from a number of powder and tablet cultures of lactic acid bacteria. Among the rest I obtained a culture of a bacillus from Dr. William H Park, of the Research Laboratories of the New York City Department of Health, which he had obtained from Dr. C. A. Herter, who had in turn received it directly from Professor Metchnikoff. This bacillus I was told was called by Metchnikoff *Bacillus bulgaris*, and was first described by Massol,[3] who obtained it from a Bulgarian Yohourth, the national sour milk beverage of Bulgaria. This bacillus produced a higher degree of acidity in milk than any of the other species, and inferring that lactic acid was one of the chief causes of the inhibitory action of lactic bacteria upon other species, I decided to use this bacillus of Massol for the experimental treatment of atrophic rhinitis. It is this bacillus which has been used throughout the research herein re-

ported. Under the microscope it appears as a slender rod. The rods vary greatly in length. At times they extend like an unbroken thread entirely across the field. At other times they appear broken into short lengths. Several sizes commonly appear in the same field. The bacillus is not motile. It takes the gram stain, grows well in milk, grows with some difficulty in broth media, and grows with still greater difficulty in solid media. The best temperature for its growth is 45° C. In some media it appears to form spores; in other media these are absent.

The Culture Medium.—In the study of the methods of cultivating these bacteria it is a pleasure to acknowledge the work of my former assistant, Dr. C. Z. Garside. To him I delegated the task of finding a favorable culture medium. The first medium tried was fresh milk whey. This was obtained in the usual manner by the use of rennet, and the fresh whey, freed from curd, furnished a clear fluid in which it was hoped the bacteria could be developed; but after several attempts this was abandoned as unsuccessful. Lactose broth was tried, with only occasional success. Dextrose broth proved to be more reliable, but even this resulted in frequent failures. Finally, Dr. Garside suggested the use of calcium carbonate in the broth in imitation of the calcium in the curd of milk, believing that because the bacillus always grew rapidly in milk there might be something in the calcium which would encourage its growth in the dextrose broth. This proved to be a most valuable suggestion, for these bacteria developed abundantly in the medium and no trouble was thereafter experienced in securing constant broth cultures at any time.

The use of calcium carbonate in liquid culture media containing sugar dates from the time of Pasteur. Hiss was the first to recommend the use of calcium carbonate in sugar broth as a means of obtaining abundant growth of bacteria, which usually develop feebly in such media. He described in his paper[4] a method for obtaining mass cultures of pneumococcus and streptococcus by the addition of one per cent. of calcium carbonate to ordinary beef bouillon. He based his suggestion on the fact that these bacteria produce lactic acid from the sugar in the medium. The increase of lactic acid in time checks their growth. Calcium carbonate neutralized the acid as it was formed, and consequently diminished to a great extent the accumulation of acid in the media, thus leaving the bacteria free from its unfavorable influence. It was, therefore, undoubtedly this same action of the calcium carbonate in our dextrose broth medium that neutralized the lactic acid as it was formed, and that enabled us to obtain such abundant growths. We used ordinary marble cracked into pieces about one inch in diameter, abundantly spread on the bottom of large flasks, holding one or two liters each of the dextrose broth. These pieces of marble were sterilized with the medium. The formula for making the medium which has proved most effective is as follows: To make one liter, take fresh extract from one pound of lean beef or veal chopped fine, extracted with one liter of water. Dried Witte's peptone, 20 grams; sodium chloride, 5 grams; dextrose, from 10 grams to 40 grams. Make up into broth in the usual way. The reaction is adjusted to the neutral point, using phenolphthalein as an indicator. As stated above, calcium carbonate in lumps is sterilized with the medium.

Cultivation.—A convenient method of keeping the bacteria alive and in a vigorous condition is to make inoculations at intervals of three or four days into tubes of milk which has been properly sterilized. Starting with this milk culture, transfers can be made to large tubes of the dextrose broth medium described above, and from these in turn transfers in larger quantities can be made to flasks of dextrose broth medium. In both cases the dextrose broth should contain calcium carbonate as described. The broth after inoculation should be placed in an incubator having a temperature of 37° to 45° C. In about 18 hours the culture will be abundantly developed. It can then be poured into smaller receptacles as required. The bacteria form a dense cloud in the broth, which when shaken shows streaks and threads, suggesting a thick, oily mucoid substance. These bacteria form an abundance of sticky, ropy material resembling mucus. For several days after the first cultivation the bacteria continue to multiply and the cloudy appearance remains. At the end of that time they settle toward the bottom of the vessel and the fluid becomes clear. Acidity of the medium increases to some extent during this time. At the end of the period of incubation, owing to the presence of calcium carbonate, the acidity does not usually extend beyond 1.2 per cent. If kept at a favorable temperature and free from the presence of calcium carbonate the acidity will increase up to 3 per cent., provided sufficient sugar is present. If the culture is kept in a refrigerator the development of acidity is prevented.

Method of Administration.—The broth culture thus prepared is used in its full strength without dilution. The inflamed surfaces to which it is to be applied may first be cleansed with warm saline solution to remove any heavy mucus, pus, or other matter which may interfere with the culture reaching the inflamed tissue itself. Theoretically the object sought is to bring the culture of lactic acid bacteria into direct contact with the bacteria which are causing inflammation of the membrane. Thus, in the nose and throat a preliminary cleansing is often of advantage, for otherwise the culture might be administered without actually reaching more than a small portion of the inflamed areas. Antiseptics should not be used in connection with this treatment. A syringe or spray apparatus is used to inject the culture fluid into the cavity and direct the stream upon the tissue surfaces. Proper precautions should be exercised to prevent contamination of the culture when removing it from its original container and in the syringe. The dose varies according to the extent of the inflammation. For the nostrils from one to five cubic centimeters is usually injected into each nostril. As a gargle in the throat or as an injection into the intestine much more is used at one time. In fact, since it may be drunk by the glass with no harmful effects so far as discovered, there is probably no danger in using large doses. I have injected five cubic centimeters into the peritoneal cavity of guinea-pigs without any effect upon the animals. The cultures have been handed to most of the physicians using them when not more than twenty-four hours old. It takes about three or four days for the bacteria to settle to the bottom of the medium. If the virtue of the preparation depends upon the presence of the living bacteria, then the culture should be used when not more than four days old. All but a very small part of it has been used within that time in the cases reported here. The instances in which it has been used after the death and precipitation of the bacteria are too few to warrant any statement as to its value at that age.

Organizing the Clinical Research.—For a number of months after the favorable culture medium was found early in January, 1908, my attempts to interest practitioners in the use of the culture for therapeutic purposes were unsuccessful. One nose and throat specialist in particular, who had under his care a number of cases of atrophic rhinitis, was on a number of occasions urged by me to try this treatment on these patients, but could not bring himself to be the first to take this step. I felt warranted in urging its use because in any event the preparation was harmless. The medium contained only beef broth and sugar and about the same amount of lactic acid as found in sour milk. The bacteria were identical with those widely used in sour milk preparations. The culture could, therefore, be freely swallowed by mouth, and I could conceive of no harm that could result from its use in the nose and throat. It was not until the first of June that I was able to secure the attention of any practitioner who would give the culture a fair trial.*

However, following my first paper on this subject, numerous inquiries were received, and cultures were sent to a number of physicians who consented to undertake the study of the treatment and to report the results to me. The majority of physicians thus lending their coöperation were men making a specialty of nose and throat work. I shall, therefore, summarize their reports first.†

Atrophic Rhinitis.—As I have before stated, the putrefactive process accompanying atrophic rhinitis first called my attention to the possibility of securing a favorable effect from the administration of lactic acid cultures in the nose. Metchnikoff had shown the power of cultures of lactic acid bacteria in milk to prevent the action of putrefactive bacteria in the large intestine; and since the mucous membrane of the nose lines one of the entrances to the alimentary canal and in atrophic rhinitis contains putrefactions and irritations from the action of bacteria, it might be expected to find relief from the same method of treatment. It is for this reason that in my communications with physicians on this subject I have suggested first of all the treatment of this disease by the culture, and consequently more cases of atrophic rhinitis have been reported to me than of any other form of inflammation. In the table below are listed the cases and the results obtained, with the names of the physicians reporting the cases:

Total	56	50	6

*The first physician who consented to give my culture a trial was Dr. H. Holbrook Curtis.

†Up to December, 1908, the cultures were produced under my direction at the Lederle Laboratories, New York. These laboratories kindly afforded the facilities for carrying on some of the preliminary work and furnished the cultures free of charge to the physicians cooperating in the research. In December circumstances made it necessary for me to remove my work to the Department of Bacteriology of the College of Physicians and Surgeons, New York. I am now producing the cultures there and furnishing them to a group of physicians who are cooperating with me in the further study of this method of treatment.

From this it appears there have been 56 cases treated, of which 50 have improved and 6 have shown no results. This in itself does not necessarily furnish convincing proof of the value of this method of treatment. There are, however, several features in the descriptions of these cases which strengthen the evidence of the good effects of treatment by this culture. The physicians engaged are located at widely different parts of the country. In the list there are represented Boston, New York, Roanoke, Va., Shreveport, La., and Fort Collins, Col. All these observers inform me that the culture "dissolves crusts." This action I did not anticipate, and it was as much of a surprise to me as to them. They also testify that the culture "destroys odor," or that the odor common to this disease disappears after treatment with the culture. It is also stated that the adhesion of crusts to the mucous membrane is loosened, so that the crusts can be easily removed, and that they are prevented from forming.

While it would not be expedient to give in detail the history of each of these cases, I will quote a few typical ones from reports I have on hand:

Dr. C. M. Haviland, Fort Collins, Col., reports a case as follows: "Mrs. L. B., age 45. Previous history good. She began two years ago to have large, hard scabs form in the nose which were difficult to dislodge. Breath offensive. No hypertrophic condition exists. No previous treatment before coming to me except common remedies, douche of salt water, etc. I tried the usual cleansing treatment for a month with negative results. On September 9 I began the use of the lactic acid bacilli after cleansing the nostrils with sterile water. By spraying under heavy pressure every alternate day the crusts began to soften almost at once, and now, at the end of two weeks, the crusting has almost entirely ceased. A few more treatments will probably bring about a cure, as the small crusts that form are soft and easily expelled."

Samuel Goldstein, M.D., Chief of Clinic, New York Throat, Nose, and Lung Hospital, among other cases reports the following: "N. R., age 30. Female. October 17, 1908. Disease atrophic nasopharyngitis. Previous history: Has had disease nearly thirteen years. Thick scabs at times sufficient to cause nasal obstruction. Very offensive odor. Treatment and results: Ichthyol and theigenol for past three years. For past four months lactic acid bacteria spray. The nares anterior and posterior were cleansed with albolene spray and the lactic acid bacteria were sprayed anteriorly and posteriorly on alternate days; nares were plugged with cotton. After three treatments the scabs became smaller and softer in consistency, and odor much less noticeable. Now the right side shows improvement. Fewer scabs and no odor. This is a very interesting case on account of marked symptoms of atrophy, with its attending discomforts and length of time under treatment. Still under observation."

T. W. Tuggle, M.D., working at the New York Polyclinic, reports an interesting series of careful observations, of which the following is typical: "Sadie K. Age 16. Disease, atrophic rhinitis, Ozena. Previous history: Suffering since infancy with nose and throat. Numerous operations gave little relief. Used applications of various kinds. The odor was extremely offensive and the crust formations were the most tenacious I have ever seen and of the consistency of putty. Much dropping into throat. Continual hawking and blowing of nose. Treatment: Three treatments each week after thorough cleans-

ing with warm saline solution; the culture of bacilli is sprayed into nasal passages and injected into antrum and sinuses with fine silver tube. After about ten treatments the putty like crusts began to dissolve and take on a flocculent character and were easily dislodged. Odor greatly diminished; also throat condition shows marked improvement, with hawking now only mornings, and only every two or three days any accumulated pus, which can be easily blown out."

Dr. Lee M. Hurd, of New York City, reports an interesting case in which, apparently, the favorable results of this treatment depended upon the continuous use of the lactic acid culture, as follows: "Mr. M. S. Age, 44. Nasal obstruction and thick secretion for three years, with headache. Examination shows large crusts in pharyangeal vault. Mucous membrane of vault and nasal cavity atrophied. Treatment: Cleaned out crusts with alkaline spray and gave him lactic acid bacteria culture to use at home, with instructions as to care against contamination of the fluid. Did not have any crusts when seen again in three days, but still complained of headache after ten days. Said that he felt quite well as long as he used the medicine, and now, October 7, he is clean and comfortable as long as he has the lactic acid bacteria solution to use. A few drops used at night suffice to keep him clean. Several times when he has run out of the solution for a couple of days the thick secretion reappeared and he felt uncomfortable. He is now quite a slave to its use and cannot do without it. The improvement seems to depend upon continuous use."

Dr. G. W. Robinson, of Shreveport, La., reports the following case: "Mrs. N. McK., age 26 years. Has had nasal discharge since early childhood. Offensive odor. Has great difficulty in getting rid of semipurulent masses that accumulate in nose. Frequently has frontal headache. Never had received benefit from treatment, although she had tried various remedies. Condition of marked atrophic rhinitis, with nares filled with crusts and purulent secretions. Ozena. Number of sprays with culture of lactic acid bacilli, four. Patient stated that following the second treatment crusts no longer formed. The secretions became less in quantity and more whitish in color. Patient disappeared from further observation. There is no doubt as to marked improvement."

These cases are sufficient to illustrate the character of the results which have been described to me in the 50 cases reported as improved. The fact that 50 out of a total of 56 cases treated all derived benefits of a similar nature seems to point strongly to the conclusion that the culture of lactic acid bacteria was responsible for the results obtained, and that the treatment may prove to be a valuable one in this class of cases.

Frontal Sinusitis.—The fact that the culture of lactic acid bacteria antagonizes to a certain extent not only the bacteria causing putrefaction, but also staphylococcus, streptococcus and other pathogenic bacteria, suggested its use in inflamed cavities discharging pus where the streptococcus and staphylococcus and other forms of bacteria might be causing the irritation. A number of cases of inflammation of the frontal sinus have been reported, as shown in the preceding table.

From this table it appears that a total of 21 cases have been treated, of which 11 are reported as cured, 6 improved and 4 no result. From these I have selected the following to describe in detail:

G. Madison Maxwell, M. D., of Roanoke, Va., reports the following case: "H. F. W., age 28 years. Chronic frontal sinusitis. Discharge through nostril and externally through openings left by operation above inner canthus in eye brows. Was operated on twice for this trouble in Baltimore. Last operation two years ago. Discharge of creamy color with disagreeable odor at times. Microscopical examination showed staphylococci and streptococci. Used lactic acid bacillus suspension on August 10 and continued same for two weeks every other day. Discharge stopped after second treatment and patient felt better than he had for a year. Has had no discharge since, excepting on November 28 a slight discharge, with some swelling over sinus region, which subsided after application of heat. Patient's general condition decidedly improved."

Dr. W. L. Culbert, New York City, reports the following: "Mrs. T. Frontal sinus infection. Had suffered from this and been treated at intervals since October, 1907. Came for treatment July 14, 1908, because of pain over right eye and to have turbinates removed. Treatment: Lactic acid suspension was injected into the right frontal sinus and into the right antrum, with the result that after six treatments the pain disappeared, the inflammation ceased and an operation was not considered necessary."

Dr. P. E. D. Malcolm, New York City, reports the following case: "W. H. B., age 53. Frontal sinus infection for ten months. Treated through sinus catheter with lactic acid suspension on October 23, 25, 26 and 28. By November 2 nose freer of secretion and patient more comfortable. November 4 got a severe cold. The treatments were continued twice a day in the same way, in addition using a laryngeal syringe. The discharge from the frontal sinus continues to diminish. The nose is considerably freer and more comfortable. Patient less susceptible to cold."

Dr. H. Holbrook Curtis, in a report which he has already published of the cases treated by him, describes similar results in inflammation of the frontal sinus.

Acute Rhinitis.—Under this head I have not attempted to distinguish coryza from other forms of acute nasal inflammations. I have no doubt, however, that there are marked differences in the character of the inflammation in the cases reported.

Physician	Cases	Cured	Improved	No Result
Chappell	40	3	..	37
Gaunt	5	..	5	..
Abbott	1	..	1	..
Personal	6	..	6	..
Total	52	3	12	37

Dr. Walter F. Chappell, of New York City, reports 40 cases of acute rhinitis, as follows: "Uniform treatment. Daily applications by myself for three days. Result: Three cases, all symptoms

abated in 12 hours; 37 cases, no special effect was noticeable."

Dr. Thomas T. Gaunt of New York City reports five cases of cold in the head treated by sprays of lactic acid bacteria culture. In all of these cases he reports excellent results.

In my own observation I have seen six cases of cold in the head treated by nasal douche of the lactic acid cultures, all of which seemed to derive marked relief from the treatment. In these cases the discharge was lessened and the swollen mucous membrane much reduced. These results are felt so soon after the administration of the cultures that the effect cannot be ascribed to bacterial action or antagonism, but must be due to some chemical or physical action of the culture medium itself.

Otitis Media.—There have been fourteen cases of this disease treated by the cultures, the results of which appear in the table below:

Physician	Cases	Cured	Improved	No Result
Kopetzky	5			5
Haviland	1	1		
Robinson	3	3		
Maxwell	1			1
Culbert	4		4	
Total	14	4	4	6

The results shown are quite irregular and not at all convincing, yet in some instances the improvement follows so closely on the heels of the treatment that it would seem that the use of the cultures is at times beneficial.

Thus, Dr. G. W. Robinson, of Shreveport, La., reports the following case: "Mr. M. consulted me about nose and ear. Diagnosis, O. M. S. A. Right empyema. Right frontal sinusitis. Performed paracentesis of membrana tympani and removed a portion of it. Middle turbinate and removed anterior ethmoidal. Frontal sinus discharge rapidly ceased and pain subsided. Discharge from middle ear continued. Began instillations in canal with lactic acid bacilli culture, and also injected into middle ear *via* Eustachian tube. Number of treatments, three. Result: Discharge ceased and opening in membrane promptly healed."

Dr. W. L. Culbert, of New York, reports the following case: "Mr. P. H. Chronic suppuration in middle ear and nose all his life. First appeared for treatment August 20, 1908. Had a discharge from right ear and left nostril. Treatment September 3. Incised both ears and injected lactic acid suspension. Sprayed nostrils with the same. Continued this treatment at intervals of several days for six weeks. By September 25 pus had disappeared from the nostril, ear ceased to discharge, eardrum healed up and patient was considered well."

Dr. C. M. Haviland, of Fort Collins, Col., reports the following case: "W. R. B., age 24. Has pulmonary tuberculosis in about last stage. Came to me on account of chronic otitis media of right ear. Perforation very small. Hearing in left ear entirely gone, due to same trouble some years ago. Treated in ordinary way by a careful cleansing and inflation, also with cold applications to mastoid. No result after six weeks. On September 24 I began using the lactic acid bacteria culture, first carefully cleansing ear with distilled water and then using the fluid through the pipette and slowly dropping same into canal, letting it work its own way into tympanum. Treatment every second day. Discharge diminished at once; then became thinner. At present time has ceased entirely. Hearing improved nearly one-third."

Ethmoiditis.—While there are a number of varieties of this inflammation and cases in which it is accompanied by inflammations in neighboring localities, I have grouped together the cases reported in which the chief trouble seemed to be properly given this name. The physicians and the cases treated are in the table below.

Physician	Cases	Cured	Improved	Negative
Chappell	2		2	
Goodale	5		2	3
Curtis	18	4	13	1
Churchill	1	1		
Yates	3		2	1
Malcolm	3		3	
Culbert	2		2	
Total	34	5	24	5

Of the 34 cases treated, 29 showed marked improvement and 5 of these were reported cured. I will give in detail the history and treatment of several of them:

Dr. J. L. Goodale of Boston, Mass., reports one of his cases as follows: "W. P. G., age 44. Reported January 5, 1907, with a right suppurative ethmoiditis, the antra, frontal sinuses and ethmoids being shown by the *x*-ray to be normal. He was treated during the following year by an argyrol spray and iodide of potash internally. Under this treatment a progressive improvement was noted until November of this year, when, although there was on the whole less discharge, a sufficient amount was formed daily to cause him annoyance. The culture of lactic acid bacteria was employed November 12 by application to the ethmoid region and also used by the patient as a spray with marked diminution in the amount of the discharge and increased comfort. At present, December 23, 1908, patient reported and expressed himself as confident that the use of the culture had been a marked benefit."

Dr. P. E. D. Malcolm of New York reports one of his cases as follows: "Mr. F. H., age fifty-six. Chronic ethmoiditis, specific. Had profuse discharge when first seen October 14. Began treatment after cleansing nose with normal saline solution by injecting serum lactic acid bacteria culture directly into ethmoidal cells. October 16, secretion diminished. October 20, complained of nose feeling dry. Small amount of discharge. October 23, very little thin discharge; October 27, very small amount, and not necessary for patient to douche nose in the morning. October 30, small amount of mucus discharge. November 6, 10, 13, 19, 23, discharge nearly normal with an occasional thin scab. No odor. These treatments are still continued twice a week. In this patient the discharge has decreased considerably so that he is now using only one handkerchief a day. Formerly four handkerchiefs were necessary while under vigorous treatment."

Dr. Wm. L. Culbert of New York City reports the following case: "Mrs. J. W. suffered with ethmoiditis for several years. Came for treatment January 4, 1908. Had operations on January 10, 13, March 11, and April 9. Discharge still continued. Lost sense of taste and smell. July 21, 1908, injected with lactic acid suspension at intervals of a few days for seven treatments. Sense of taste and smell have returned but are not constant. The discharge has diminished. The inflammation has considerably decreased."

Dr. H. H. Curtis has already reported a number

of cases of this inflammation in the papers he has published, and the results of the treatment correspond to those described above, in that the discharge was much diminished.

Antrum.—While inflammations of the antrum accompanied a considerable number of the cases already reported, yet there have been only eight cases in which this inflammation was the chief feature. Of these, four are reported as improved and four as having shown no result after treatment with the cultures of lactic acid bacteria.

Dr. Lee M. Hurd of New York reports a case as follows: "Mrs. C., age thirty-five. Has complained of nasal obstruction and polypi for one year. Examination revealed antrum disease, probably from carious teeth; also some ethmoidal infection. The antrum was opened into nasal cavity under inferior turbinate. The purulent discharge remained and the ethmoids continued to secrete white pus. This did not diminish under several months' local treatment with antiseptics. Beginning September 17, I injected solution of lactic acid bacilli into the antrum and middle meatus every other day without other treatment. The discharge has diminished and became more mucoid, with less color, but at the end of three weeks has not entirely disappeared. The improvement is considerable."

Dr. W. L. Culbert of New York reports a case as follows: "Mr. R. M., age twenty-six. Inflammation of both antra with discharge of pus. May 23, 1908, right antrum opened. May 26, inflammation spread to both ears. May 28, operated on for double acute mastoiditis. Since that time discharge from nose and one ear has continued. January 26, sprayed nose with lactid acid culture. The spray hurt him, but pus stopped. After a few days pus returned. Sprayed again and pus stopped. After a few days pus again returned and was again sprayed. This was repeated several times. Finally lactic acid suspension was injected into ear and Eustachian tube and the pus discharge ceased."

Chronic Rhinitis.—Some cases have been reported under this title which are similar to those classified under some of the other titles before mentioned. Five cases have been handed in under this head, all of which are reported as improved. Dr. C. H. Wood of Glendora, Cal., describes a case as follows: "Patient with chronic rhinitis and nasopharyngitis of twelve years' duration. The patient has undergone at the hands of a number of competent physicians various treatments without considerable benefit. I injected the nose daily with the culture lactic acid bacteria through small syringe and sterile rubber tube. The results with the suspension have thus far been very gratifying. There is a very marked reduction in the amount of the discharge, the use of much fewer handkerchiefs, disappearance of the odor and of headache, with greater facility in breathing, and a general improvement in the patient's physical condition and sense of well-being."

Dr. E. L. Meierhof of New York City reports a case as follows: "Miss F. H., age ten. Mucopurulent rhinitis and adenoids. Previous history, difficulty in breathing by night and day. Examination showed mucopurulent discharge, suppuration from both nostrils. Adenoids were removed. No improvement in nasal discharge or breathing. The culture of lactic acid bacteria was sprayed into the nostrils every second day. After two treatments there was no further evidence of the muco-purulent secretion. An operation on the septum is needed to further improve the breathing."

Hay Fever.—There have been eleven cases of hay fever treated, of which ten are reported as improved and one without result. Eight of these were treated by Dr. H. H. Curtis, and details of his results appear in papers he has published.

Dr. Thomas T. Gaunt of New York City reports two cases in which he describes the results as "fair."

Dr. Lee M. Hurd of New York City reports the following case: "Miss N. B., age twenty-eight. Hay fever. Treated by spray with culture lactic acid bacteria three times a week. August 25, hay fever had disappeared. August 27, 29, 31, September 2, still disappeared, but continued under treatment three times a week until September 19. October 13, has had no lactic acid culture for two weeks. Feels much better. Does not sneeze and is able to breathe freely. Patient thinks improvement is due to medicine, as she always continues with hay fever through September. As there is a large neurotic element in hay fever it is hard to know how much benefit is due to the remedy."

It is difficult to attribute any favorable result in hay fever to the disinfecting or germicidal action of the culture, as hay fever is not considered to be due to bacteria. The culture of lactic acid bacteria is reported by a number of the observers to have an effect upon erectile mucous membrane similar to adrenalin, but not so rapid. That is to say it shrinks the swollen tissues. Possibly the results reported in hay fever are due to this action.

Tuberculous Sinuses.—On the theory that the cultures of lactic acid bacteria might antagonize the tubercle bacilli and the bacteria causing a secondary infection in sinuses and abscesses, a series of cases were treated at the Hospital for Ruptured and Crippled, under the direction of Dr. N. B. Potter. In all there were ten cases; and these included hip disease, caries of the spine, osteitis of the knee, and several others. In all of these cases the culture was injected as far into the sinus and abscess as possible. No permanent benefit resulted from this treatment. There were frequent instances in which the temperature was markedly reduced after injection and some of the cases showed temporary improvement, but in no case was the inflammation definitely checked in a way that would point to the treatment as producing that result. There are certain physical difficulties in bringing the fluid culture into direct contact with the inflamed areas in this class of cases; and this may be one reason why the treatment was not effective. The cultures of lactic acid bacteria may of course have no effect upon tuberculous processes under any circumstances. The experiments outlined above are not conclusive in any event.

Gonorrhea.—There have been two series of cases of this disease treated; one at the New York Post-Graduate Hospital, under the direction of Drs. De Santos Saxe and Conrad Meyer, and the other at the City Hospital, Blackwell's Island, under the direction of Dr. Frederick A. Sutton. None of these cases is reported in detail, but the general results are given in the table below:

Physician	Cases	Cured	Improved	No Result
Saxe	15	1	14	..
Sutton	13	2	10	1
Butler	1	..	1	..
Total	29	3	25	1

Commenting on his cases, Dr. Saxe says: "The duration of the treatment in each instance was about two months. The cases were all acute inflammations of the ordinary type; that is, cases which did not present extreme signs of acute inflammation externally. The duration of the disease previous to the beginning of treatment varied from one to fourteen days. The treatment consisted of injection of lactic acid bacteria three times weekly. The results as thus far observed have been as follows: In no case has there been anything like an aborting of the disease, but with one exception all cases ran a very mild course. Only two of the fifteen cases developed posterior urethritis. In every case the injection seemed to lessen the discharge. In five cases the discharge ceased altogether after the eighth day. Of the group of cases observed only one patient can be said to be completely cured thus far. All the cases received routine treatment of emulsion of sandalwood oil internally. While the above results seemed to be favorable they are not convincing as regards the actual effect of lactic acid bacteria." The cases treated by Drs. Saxe and Meyer were all in males.

Dr. Sutton of the City Hospital reports nine cases of urethritis, six of which were improved, two cured, and one not improved by injections of the culture. He also reports four cases of vaginitis, all of which were improved. One case of mucous patch in the throat and one case of chancroids were greatly improved by swabbing with the lactic acid culture. Of the gonorrheal cases, Dr. Sutton says: "All cases except one showed marked improvement in the nature and amount of discharge almost from the first injection. Injections were given daily, about four drams being used in a small syringe."

Cystitis.—Two cases of cystitis have been reported as follows:

Dr. Biddle R. Marsden of Chestnut Hill, Philadelphia, reports the following case: Pyelitis and cystitis of ten years standing, caused by passage of clots down the ureter. Could not hold urine more than one hour. Bladder holds only nine ounces of salt solution. Treated by washing the bladder with normal salt solution, followed immediately by injection of 5 c.c. of lactic acid culture into the bladder five times weekly for three weeks. Result: The improvement in the urine has been marked, especially in the last few days. Clots of mucus and pus are getting much less. There is considerably less blood in the sediment. Burning and irritation markedly improved. Less pain in the region of the kidney. Can now hold urine three or four hours. Bladder now holds thirteen ounces. On the whole he is fifty per cent. improved.

Dr. Sutton of the City Hospital, New York, reports: "One case of cystitis after operation for stone gave a free discharge of pus in the urine, and rapidly cleared up under the treatment with the culture which was injected into the bladder."

Leucorrhea.—Reports have been handed in concerning seven cases of leucorrhea. Five of these were treated by Dr. Harold B. Judd of New York City, under the direction of Dr. N. B. Potter. Two of these were improved by the treatment and three showed no apparent result.

One of Dr. Judd's cases was as follows: "Miss M. S., thirty-three years of age. First came to dispensary April 10, 1908. Suffering from very marked leucorrhea of three years' duration. Pain in back. No gonococcus. No displacement. Bilateral laceration of cervix. Treated with argyrol and ichthyol three times a week. Discharge and pain somewhat improved. July 3 to July 27 culture of lactic acid bacteria used three times weekly. Amount of discharge steadily decreased until at the present time there is practically none."

Dr. W. W. S. Butler of Roanoke, Va., reports two cases of leucorrhea, in both of which treatment with lactic acid bacteria was successful. One of these cases was as follows: "Mrs. D., age thirty. Three children. Complained of dragging sensation. Pain on both sides of pelvis. Poor condition. Uterine hyperplasia with prolapse, ulceration of cervix with profuse discharge. Tender in tubal region of both sides. Used constitutional treatment and uterine irrigations of tincture of iodine from time to time, but these gave only temporary relief. August 21, treated with cultures of lactic acid bacteria at intervals of five days. At the end of that time condition was as near normal as possible."

Under the direction of Dr. Frank R. Oastler, at the Vanderbilt Clinic of the College of Physicians and Surgeons, New York City, a number of cases of leucorrhea have been treated without apparent benefit.

Diarrhea.—One of the most obvious localities in which favorable results might be expected from the application of the culture of lactic acid of bacteria is the intestine. The use of milk soured by bacteria has been demonstrated by Metchnikoff and his followers to be of great benefit in certain types of intestinal irritation. The injection of broth cultures of lactic acid bacteria per rectum seemed, therefore, to warrant the expectation of good results. A series of eleven cases of infant diarrhea were treated at the New York Infant Asylum by Dr. W. C. Williams. All were of severe acute type. They were treated by injecting the culture of lactic acid bacteria through rectal tubes as high as possible into the colon. In two cases the temperature fell to normal and discharges ceased, and patients completely recovered. In four cases the temperature fell following the treatments and stayed down to normal from two to five days, and discharges were somewhat diminished, when reinfection occurred. In five cases the treatment was without effect.

In addition to this a series of cases were treated with cultures by Dr. Charles G. Kerley, which he has reported in a paper of his own and in which the results were not favorable.

There are some factors which may account to a certain extent for the failure of the treatment on this class of cases. One is that if the seat of inflammation is in the small intestine it may not be reached by the rectal irrigations. A case has been reported where success was achieved by administration of the culture per mouth after the treatment per rectum produced no result. If the type of inflammation is "fermentative" it may be one which is caused by bacteria that are not antagonized by this culture

Surgical Cases.—The cultures have been used by several surgeons with great variation in the results. Dr. George E. Brewer at the Roosevelt Hospital, New York, used it in five cases of acute and chronic suppurating wounds and sinuses. He says of it: "It seemed inferior to the iodine preparations in pyocyaneus infection and formation, and to bichloride in the ordinary mucous infections. I must say, however, that in one of two instances it seemed to act very promptly in check-

ing the colon bacillus infection. As a rule, however, the cases do not do as well as the cases treated by the ordinary routine hospital methods."

Dr. John Rogers of New York City reports an interesting case of general peritonitis as follows: "Miss M. S., seventeen years old. Developed appendicitis about October 25, 1908. On November 11, there was every evidence of general peritonitis. Leucocyte count 29,000, polynuclears 88 per cent., temperature 102°, pulse 130, respiration 40. The abdomen was opened and pus found diffusely throughout the peritoneal cavity. This pus was the pure streptococcus. The pus was hastily flushed out and the contents of a two-ounce bottle of your culture of lactic acid bacilli poured into the abdomen and scattered around as much as possible by my hand, though the distended intestine prevented a thorough distribution. The wound was closed with the exception of a small tube drain down to the appendix, which was not removed. When the patient was returned to bed the pulse was 160 and the extremities cold. The next day the temperature and respiration were nearly normal and the pulse 100; and about a dram of your emulsion was injected through the drainage tube. This was continued daily until November 25. Then the abdomen was opened again on the left side and a small amount of pus evacuated from around the left kidney. The secondary collection of pus in the abdomen after a generalized infection is not uncommon. The injection of your emulsion through the second drainage tube was continued for a day or two longer. This patient is convalescing and sits up to-day for the first time." Dr. Rogers later reported that the patient went on to complete recovery. In addition to this, Dr. Rogers treated eight other cases of large localized abscess in the abdomen due to appendicitis by evacuating the pus and filling the cavity with two ounces of the lactic acid suspension. There have been no deaths in any of these cases and no ill effects. The lactic acid bacilli seemed entirely harmless. "But," Dr. Rogers says, "I do not think the culture has shortened the period of convalescence in these cases."

Dr. W. Francis Honan also reports a case of acute diffused peritonitis treated with this culture. "Mr. A. B., admitted to hospital November 5, 1908. Leucocyte count 21,000. Polymorphonuclears 91 per cent. Cultures from infection of peritoneal cavity (after operation) showed the presence of *B. coli communis* and streptococcus pyogenes. Symptoms of acute indigestion followed by obstinate constipation and apparent obstruction of the bowels brought him to the hospital. On admission temperature was 99.6°, pulse 138, respiration 28. Abdomen distended. General pain on palpation. An operation two hours after admission. Incision through posterior sheath of rectus. Immediate gush of pus and turbid fluid. Extensive involvement of peritoneal cavity and contents. Appendix gangrenous. Amputated with cautery. Two ounces of lactic acid bacteria culture was poured into the peritoneal cavity and on to stump of appendix. No flushing attempted to remove exudate. Wound closed about the drains. Patient returned to bed and placed in Fowler position. Saline absorption plan put in operation. Nuclein solution every six hours hypodermically. Drains removed on fifth day. Wounds dressed daily with lactic acid culture. Convalescence uneventful and patient left hospital in about three weeks."

Dr. Joseph A. Devlin, working under the direction of Dr. Rogers at St. Francis' Hospital, reports the following surgical cases:

"Case I.—Granulated wounds following operation for strangulated hernia. After second day the skin sutures had to be removed to allow discharge to escape. The granulated surface which followed was very indolent and the discharge was excessive. This was the condition when the lactic acid bacteria was first used. Two days later discharge very much lessened and granulations resumed a healthy red color.

"Case II.—A child with a sinus leading to a tubercular os calcis. A mixed infection existed in this case and thus far there has been no diminution in the discharge, although treated by injections of the lactic acid bacteria on two occasions. Five days after the first injection the inflammatory process which was getting under way around the sinus had entirely disappeared. The ankle is still discharging on account of necrotic bone.

"Case III.—A large sinus on inner side of thigh following operation for osteomyelitis of femur. The femur is visible for three inches of its length. Necrotic areas are studded over the exposed portion of the femur. Discharge horribly offensive. Washes and deodorants used with no avail. In this case culture of lactic acid bacteria was poured on the surface. After two applications discharge for the first time in three months became practically odorless, gauze dressings less saturated and discharge much thinner.

"Case IV.—Empyema of the chest. Discharge three ounces of thick greenish pus every day. Culture of lactic acid bacteria injected through the sinus tube every other day for three days. The discharge became less and less, the last was not over one ounce in twenty-four hours, and it was thinner and less offensive in odor."

In addition to these surgical cases, there have been a series of varicose ulcers of the leg treated at the Hudson Street Hospital, details of which have not been received, but verbal reports state that considerable improvement was noted in those cases which were treated by using the lactic acid cultures as a wash and on the dressings.

Maxillary.—H. S. Dunning, D.D.S., carried on a series of experiments at the New York College of Dentistry. He reports five cases of inflammation in the maxillary bones and palate treated by injections of lactic acid bacteria and all of which were improved by treatment. One of these in detail was as follows: "Young woman, age twenty-one. Condition of gums and teeth poor. General health good. Infection of outer portion of inferior maxillary bone from bicuspid to bicuspid. The infection was of seven weeks' standing, and included fistula in the face and the removal of small pieces of bone. There were many sinuses leading from the soft gum tissues to the bone. Pus flowing freely. Injections of the culture of the lactic acid bacteria were given several times weekly, allowing the fluid to remain in each sinus. After about four weeks only one sinus remained open."

Another case. "A man, forty years old. Condition of gums poor. Bad teeth. Poor breath. Poor health. Suspected tuberculosis. The lower jaw in the region of the third molar on the right side deeply infected and a discharge of green pus. Bad odor. The infection was of six months' standing. After several injections of the lactic acid bacteria the condition was cleaned up considerably. Patient disappeared from observation."

Gonorrheal Ophthalmia.—The following table shows the results of the treatment of gonorrheal ophthalmia with lactic bacilli culture:

Physician	Cases	Cured	Improved	No Result
Cutler.	17	15		2
Sutton.	2	1	1	..

Dr. Coleman W. Cutler, New York City, reports seventeen cases of gonorrheal ophthalmia in children occurring in his service at the New York Foundling Hospital and there treated under his direction. Of these he says: "In two cases ulcers of the cornea were present on admission. These children died soon after from marasmus. The corneal ulcers were not influenced by treatment. All the others recovered from the opthalmia without corneal involvement. The duration of the disease in these cases was usually brief, but as the routine was followed as well as the lactic acid bacillus suspension it is not possible to attribute the favorable results to one part of the treatment more than to another. The following four cases, however, would seem to justify the giving of especial credit to the suspension of lactic acid bacillus.

"Case IX.—A. Z., age three years. Congenital syphilis. Ulceration of the septum. Inunctions. Syrup ferri iod. Gonorrheal ophthalmia both eyes. Smear showed numerous gonococci, much secretion, lids swollen. Treatment: Silver nitrate, 2 per cent., once; protargol, 10 per cent., q.2.h. for one day, after which suspension lactic acid bacilli t. i. d., and boracic acid. Improvement rapid, secretion scanty in three days. In one week no secretion, smear negative.

"Case XI.—W. G., age two weeks. Much secretion and swelling. Smear positive. Inflammation continued in spite of silver nitrate and protargol. Suspension of lactic acid bacilli used on third day and t. i. d. thereafter. Secretion diminished rapidly and cure in one week.

"Case XV.—R. G., age two weeks. Moderate secretion. Smear positive. Silver nitrate used once; protargol, 10 per cent., q. 3 h., with no improvement. Then suspension of lactic acid bacilli t. i. d. Rapid improvement and cure.

"Case XVII.—D. S. Mild ophthalmia. Smear positive. Silver nitrate and argyrol. After two days secretion still profuse. Then suspension of lactic acid bacilli. Eye dry in four days."

Dr. Frederick Sutton, at the City Hospital, Blackwell's Island, N. Y., reports two cases of gonorrheal ophthalmia, one of which was "cured and left no opacity." The other "eyes improved rapidly. Pus after first day's treatment became thin and less yellow." Then the treatment was changed, due to removal to another ward.

Conjunctivitis.—In addition to the cases of gonorrheal ophthalmia, Dr. Cutler reports that "one case of pneumococcus conjunctivitis and one of diplobacillary conjunctivitis (Morax-Axenfeld) and eight cases of catarrhal conjunctivitis without microscopic diagnosis were treated with the suspension of lactic acid bacilli alone with success, the secretion diminishing as rapidly as with the ordinary measures."

Summary and Conclusions.—The lists of the groups of cases treated, with the results noted, are summarized in the following table.

In reflecting upon the apparent action of these cultures the question obviously suggests itself whether the action is due to the living bacteria themselves, or to the lactic acid, or to other products in the culture medium. I will not attempt to discuss the question here. These matters are unsettled and will naturally form a part of the further researches on this subject.

Disease	Cases	Cured	Improved	No Result
Atrophic Rhinitis	56		50	6
Ethmoiditis	34	5	24	5

Reviewing the conduct of this research and the facts which have been gathered up to date it must be admitted that the affair has been somewhat unconventional, and perhaps unscientific. I am fully aware that carefully controlled laboratory experimentation in the study of the species of bacteria and of culture media and of their effect on each other and on animals should precede the studies on human beings. I am also aware that a selected set of cases and the extension of treatment over a long period of time, accompanied by laboratory examinations of exudates from the sites of the inflammations treated should precede any claims as to the value of the treatment. But my work has been done in the midst of an active practice of bacteriology. Interruptions due to this fact have made any regularly organized research impossible. In view of this I do not present the facts that I have gathered as a conventional piece of research, but rather as circumstantial evidence.

How much value should be attached to the results obtained by treatment with the culture of lactic acid bacilli is largely a matter of individual judgment. It is possible to err on the side of enthusiasm, on the one hand, and on the side of caution and timidity on the other. In my opinion the treatment of some inflammations caused by infectious bacteria which can be reached by a spray or wash of the culture of lactic acid bacteria used in this research has considerable value. A few things have been learned by the work that may be even more positively stated:

1. That the bacillus of Massol can be grown abundantly in dextrose bouillon by the addition of lumps of calcium carbonate.

2. That the use of these cultures as a wash or spray on inflamed surfaces or cavities often diminishes the discharge upon such surfaces or cavities.

3. That the use of these cultures often diminishes odor caused by putrefaction.

4. That the treatment sometimes reduces swelling, especially in the erectile tissues of the nose.

5. That both acute and chronic inflammations caused by infections sometimes appear to be checked when their seat can be reached by an injection of these cultures.

6. That the use of the cultures seems to be accompanied by no special danger and that they cause no irritation.

Further study of the treatment seems to be warranted from the results obtained. This study is now being continued by me in conjunction with a number of physicians who are using the treatment. I shall make further reports of the progress of the research in later papers.

If this treatment becomes established, then another weapon will have been placed in our hands for fighting infections. It will mean fighting bacteria with their own weapons; literally, "germ fight germ." The success of one species of bacteria cultivated in one culture medium will suggest the investigation of other species of bacteria and other culture media; and among these may perchance be found not only cultures of general value, but some of special value in combating particular infections of one sort or another. It may be that bacteria cultivated in laboratory media, together with their products, are destined to play an essential part in the warfare against infectious disease.

DIRECT BLOOD TRANSFUSION — ITS TECHNIQUE AND THE INDICATIONS FOR ITS USE.

BY A. A. BERG, M.D.,

NEW YORK,

ADJUNCT SURGEON TO MT. SINAI HOSPITAL.

THE transfusion of blood is not a new therapeutic procedure. It was known to the ancients, was practised occasionally in the Middle Ages, and with great frequency in the seventeenth century after Harvey had discovered the circulation of the blood. The blood of animals and man has been employed for the purpose, the early operators using especially the blood of lambs. But though blood transfusion is not new, the technique of its performance at the present time is entirely so, and with this new technique the dangers that have hitherto attended the operation have been entirely eliminated. It is because of this new technique and the consequent newer and wider indications for the employment of blood transfusion that the writer brings the subject before you.

By the modern method of transfusion the blood flows directly and immediately from the artery of the donor into the vein of the patient. There is no intermediate system of tubes connecting the donor's artery and the patient's vein, through which the blood must pass. By the present method the blood is always in contact with the healthy intact intima of the blood vessels; it never touches any foreign substance. In this way is avoided the greatest danger that attended the older methods of transfusion, viz., the clotting of the blood in the intermediate tubes and the introduction of these clots into the circulating blood stream of the patient, and the consequent lodgment of emboli in the internal organs.

Another danger that has heretofore attended the practice of transfusion has been the breaking down or dissolution—hemolysis—or the agglutination of the recipient's blood by the newly transfused blood. It is evident that if the transfused blood will hemolyze or agglutinate the blood of the patient, harm instead of good will be done by the operation.

It has been known for some time that the blood of an animal of one species, when brought into contact with the blood of an animal of another species, will dissolve (hemolyze) the red blood cells of the latter; and it has also been demonstrated that the blood of animals of the same species will occasionally act in such hemolytic manner toward each other. These hemolytic phenomena must have occurred in the times when it was customary to use for transfusion into human beings the blood of lower animals, especially lamb's blood; and this undoubtedly explains the bad and often fatal results that attended this practice. In the human species it does not often happen that the blood from one individual will hemolyze the blood of another, but the possibility exists, and consequently no blood transfusion should be attempted, except in cases of urgent necessity, without previously determining whether the donor's blood will hemolyze the blood of the recipient. The test can be rapidly and easily made in any well equipped laboratory.

Of less frequent occurrence, in the former days of transfusion, was air embolism, an accident which is entirely averted with the present method of operating.

The improved technique of the operation of blood transfusion and the elimination of the dangers that have hitherto attended it have led to a readoption of the practice, and a wider field for its employment has been mapped out. The question of its value in these new fields is, however, still an open one, and will be decided only by further trial and experience.

Before interesting ourselves with this part of our subject it will be well to describe the visible and physical effects of a blood transfusion on a patient, and this can be best done by reciting the observations in a recent case.

Anna K., a governess, aged 35, was exsanguinated from repeated hematemeses, due to an open gastric ulcer; to stop the bleeding a posterior gastroenterostomy, with excision of a pyloric ulcer, had been done. Her hemoglobin percentage was 12, the red blood cells 2,000,000, and her general physical condition very much deteriorated. The operation had checked the bleeding, and for five days succeeding the operation everything possible was done to build up her condition, but to no avail. She gradually became more apathetic, her pulse more thready and feeble, and it seemed as though she would die at any moment. As a last resort blood transfusion was performed, a sister giving the blood. For ten minutes after the sister's radial artery had been anastomosed to the patient's median basilic vein no apparent change was noted. Then the stupor lightened, the patient opened her eyes, commenced to ask questions, and was able to recognize her friends. Her pulse became fuller and of better quality; her hemoglobin rose gradually to 60 per cent. After thirty minutes of the transfusion she was in good condition, rosy color, mind clear, recognized her friends, and thanked her sister for the sacrifice she had made. The striking change from deep stupor due to the cerebral anemia to a normal mental state was very impressive.

As regards the technique of the operation, those who are skilful with needle and thread will prefer the end-to-end or end-to-side anastomosis of a superficial artery like the radial with a superficial vein like the saphenous or cephalic, after the method of Carrel. The basic principle of the anastomosis is to bring the intima of the artery everywhere into contact with the intima of the vein. The vessels to be anastomosed are first exposed and freed from their surroundings for a distance of one to one and a half inches, and clamped proximally and distally with a soft serrefine forceps.

The artery and vein are then divided, if end-to-end anastomosis is to be made; or an incision is made into the side of the vein if a lateral anastomosis is to be effected. The cut ends are lightly covered with sterile paraffin oil or vaseline, and two guide sutures are passed to hold the vessels lightly in contact. Then, with a continuous through-and-through suture passing from the outside of one vessel to its inside, and vice versa in the other vessel, the anastomosis is perfected. The suture material should be one of the component strands of fine twisted silk, and the needles are No. 16 straight cambric variety.

The vessels should be handled as little and as gently as possible with fine iris forceps whose ends are kept covered with liquid paraffin or vaseline, and throughout the entire procedure the parts should be kept moist with warm saline solution. With vessels of the caliber of the radial artery and saphenous or cephalic veins, such anastomosis by suture is not at all difficult, nor is it a very time-consuming procedure.

Those who are not sufficiently adept with needle and thread as to warrant their attempting a suture anastomosis will find the method of anastomosis described by Crile an excellent and speedy procedure. Taking the magnesium rings which Payr used for arterial anastomosis as a model, Crile has constructed a small cannula by which, after the method of Payr, a rapid and excellent end-to-end or end-to-side anastomosis can be effected between the artery of the donor and the vein of the recipient. These cannulæ are one-eighth of an inch long and of varying caliber, four different sizes being supplied in a set to suit the caliber of the vessels that are to be anastomosed.

For the end-to-end anastomosis the length of Crile's cannula is just right, but for an end-to-side anastomosis, which with this method is much more readily done, it is the writer's opinion that they should be about half as long again, *i.e.* 3-16 instead of 2-16 of an inch. Each cannula has affixed to it a small handle by which it can be grasped and easily manipulated.

In this method, the artery and vein are exposed as in the suture operation. After dividing the artery and stripping off its outer adventitious coat, three fine guide sutures are passed through its wall at equidistant points. These sutures are threaded through the cannula, and by means of them the vessel is drawn through the latter; then its wall is everted over it in cuff-like manner, and secured in this position by a silk ligature. The outside of the cannula is thus covered by a cuff of the artery with the intima on the outside. After a little experience this step of the operation is easily and rapidly performed. The vein is now laterally incised or nicked and the cannula covered by the cuffed artery is inserted therein and held in place by a suture.

If an end-to-end anastomosis is to be made, the vein is slipped over the cuffed cannula. In either case, the intima of the artery is everywhere in contact with the intima of the vein. The end-to-end anastomosis takes a few moments longer to make than does the lateral anastomosis. Another advantage of the latter is that a much smaller vein suffices than for the end-to-end junction. This is especially important when we have to deal with new-born infants or very young children. One of the chief advantages of anastomosis by the Crile cannula lies in its simplicity. The tube itself is very simple, and with a little practice the entire operation can be easily and rapidly done. A number of modified cannulæ have been suggested, but they have no advantages over the Crile, for they are more complicated and do not add anything to the ease, speed, or safety of the operation.

A very important question that comes up in blood transfusion is the amount to be transfused, and how this is to be measured.

As yet there is no means of measuring the amount of blood that is transfused. It has been the custom to depend upon the increase in hemoglobin percentage of the recipient as a rough indication of the amount of blood transfused. The percentage of hemoglobin in the blood of the recipient and donor is taken immediately before the anastomosis is effected and every 10 minutes during the progress of the operation. From a normal adult man we can usually transfuse sufficient blood to raise the hemoglobin of an adult donee to 65 or 70 per cent. Sometimes the hemoglobin percentage of the recipient increases rapidly, especially when it is low at the outset of the transfusion. Thus we have seen it increase from 20 per cent. to 50 per cent. in 15 minutes; and again in an 8-day infant from 10 or 15 per cent. to 105 per cent. in 12 minutes, the donor in each case being an adult man.

The rapidity of increase depends upon the rate and amount of the flow of the blood into the recipient's vein, and these in turn upon the caliber of the donor's artery and the pressure therein, and the size of the recipient's vein and the pressure therein, and finally upon the character of the recipient's blood.

We must not expect that the donor's hemoglobin will show *during the transfusion* a decrease in percentage proportional to the increase in the recipient. For the blood remaining in the donor has not been deprived of its hemoglobin. It is exceptional for the donor's hemoglobin, during the transfusion, to fall more than 10 per cent., even though the recipient's hemoglobin rise 40 to 50 per cent. It is only a number of hours after the operation, when sufficient fluids have been absorbed from the intestinal canal and tissues to restore the volume of the blood and thereby dilute the remaining hemoglobin, that a material decrease in the hemoglobin percentage is to be noted. To avoid taking too much blood the writer would suggest that in addition to taking the hemoglobin percentage, we record also the donor's blood pressure during the entire operation, and should this fall to 80 m.m. the transfusion is to be stopped.

The improved technique and the precautions that are observed to prevent hemolysis, as above briefly outlined, have removed all the dangers hitherto attending direct blood transfusion, and in consequence thereof the surgeon and internist have both sought to widen the field of its usefulness. Though the writer is very enthusiastic about the value of blood transfusion in certain conditions, he does not believe it to be a panacea for all ills, nor even for most

maladies that human flesh is heir to. Further and more extended experience will soon furnish sufficient facts to more rationally and sharply establish the indications for its employment.

Up to the present direct blood transfusion has been found of value in the following conditions:

Severe acute hemorrhage. In this condition it far surpasses intravenous saline infusion, for in addition to simply adding to the volume of the circulating fluid, as is done by the latter, it furnishes living blood cells and plasma to the exsanguinated patient. Further, the good accomplished by a blood transfusion is likely to be more lasting than that from an intravenous saline infusion.

It goes without saying that the bleeding vessels must be secured, either before or while the transfusion is going on.

For the condition of shock due to acute severe hemorrhage, direct blood transfusion acts most efficiently. The following case will illustrate this:

The patient, a young man about thirty years of age, had repeated attacks of bleeding from a duodenal ulcer. When admitted to the hospital he was exsanguinated, apathetic, and semi-stuporous, had a whitish yellow color, and a scarcely perceptible pulse. The bleeding had recurred in spite of the administration of internal remedies. Though it seemed as if further bleeding would undoubtedly cause the patient's death, yet surgical interference could not be considered in his desperate condition. We consequently determined to wait and to employ further internal remedies, in the hope of preventing renewal of the bleeding.

After 24 hours there were evidences of renewed hemorrhage from the ulcer—the hemoglobin count falling to 18 per cent. in the course of the day. The patient was semi-conscious, the eyes and cheeks sunken, the expression and color lifeless. Blood transfusion was determined upon, and this to be followed by immediate laparotomy so as to control the bleeding. A brother consented to our proposal and we soon had his radial artery anastomosed to the median basilic vein of the patient. Within ten minutes after the transfusion was started the color of the patient's face became pinkish, the cheeks and eyes fuller, and from a state of deep apathy he began to take an interest in the affairs about him and thanked his brother for his devotion. His pulse became fuller and more regular, and the transfusion was continued until the hemoglobin reached 60 per cent. An immediate laparotomy and posterior gastroenterostomy were done. The shock was well borne and the patient reacted nicely.

But brilliant as are the results from blood transfusion in acute hemorrhage and the shock arising therefrom, these have not been found to be so good in conditions of shock due to other causes, *e.g.* severe trauma, perforations of hollow viscera, etc. Further experience is necessary before a fair conclusion can be reached as to the value of the procedure in shock from these latter causes.

Another condition in which blood transfusion has been employed is in the hemorrhagic diathesis, but here again there is need of much more research and clinical observation before a final decision can be reached as to its value. The hemorrhagic diathesis or pathological bleeding, *i.e.* the tendency that some individuals have to repeated, often profuse, and sometimes fatal capillary bleeding, is either inherited, as in hemophilia, or acquired, as in many cases of anemia, jaundice, purpura, asphyxia, acute alcoholism, and other toxic conditions.

It would be entirely foreign to the object of this paper to enter into a discussion of the causes of the capillary bleeding in these various diseases, nor could the writer place before you any satisfactory conclusion in this regard, for some authorities maintain that the fault lies in an alteration of the capillary walls, others insist that the cause is to be found in a delayed coagulability of the blood, and still others attribute the bleeding to both these causes. Again the exciting cause of the structural changes in the capillary walls and of the delayed coagulation time of the blood is by no means determined. Thus, some hold that infectious agents play a leading rôle therein, others advance the toxic theory, and so on.

It is evident that blood transfusion can be of value only in those cases in which changes in the blood account for the hemorrhage, and where the addition of fresh normal blood to the patient would supply the elements that are deficient in his own blood. But before the final word can be said in this regard, more light must be shed upon the pathogenesis and exciting causes of the hemorrhagic diathesis. This evening I shall consider only what has been the clinical experience with blood transfusion in hemorrhagic states.

Carrel and Lambert were able by the transfusion of the father's blood into a baby only a few days old, to check bleeding that seriously threatened to end the child's life. Crile, in a case of cholemia from obstructive jaundice due to biliary calculi, in which there were numerous hemorrhages, was able by blood transfusion to check the bleeding.

During the past summer the writer has had occasion to transfuse an exsanguinated baby aged seven days, suffering from numerous hemorrhages from the skin and mucous membranes. The child had been referred to the pediatric service of Dr. Koplik at Mt. Sinai Hospital by Dr. Schwarz. There Dr. Henry Heiman and Dr. Schwarz used all known medical means to stop the bleeding, but to no avail. It was found that the child's blood had no tendency whatever to coagulate. It remained in a fluid state for 24 hours, but when a drop of its father's blood, or of another adult blood was added to it, coagulation took place within five minutes. On the assumption that the child's blood was deficient in those elements which cause coagulation, and also guided by the brilliant result attained by Carrel in Lambert's patient, transfusion of the father's blood into the baby was proposed and accepted, and the father's radial artery was anastomosed into the femoral vein of the patient. Just before the transfusion, the baby had no pulse in the radial artery, it was deathly pale, and its respirations were superficial; there seemed to be no life whatever, though a faint cardiac pulsation could be noted. Death certainly seemed imminent at any moment. The wound in the thigh did not bleed.

The operation was technically difficult, first because of the small size of the patient's vessels, and second because the veins themselves were collapsed and therefore difficult to locate. Five minutes after the anastomosis was effected the child's hemoglobin rose from 12 to 20 per cent., its color was decidedly pink, the wound in the thigh commenced to bleed, the respirations were deeper, and the radial pulse could be felt. After another five minutes the color was red, the pulse was of good quality, hemoglobin 60 per cent., respirations full and deep. Within the next few minutes the child became rosy red, and then after another few minutes somewhat bluish,

with impaired respirations. Evidently too much blood had been infused, and it was thought that it would be necessary to allow some of it to escape. An immediate stoppage of the transfusion, however, enabled the infant's heart to adjust itself; the respirations, color, and pulse rate became normal, and the child fell asleep. Its blood now coagulated in three minutes, the time of the coagulation of the father's blood. The bleeding from the skin or mucous membranes ceased for the time, the child took nourishment well, and seemed to be normal. The following day the time of its coagulation was three minutes, the second day about the same; the third day it was about five minutes, the following day seven minutes, and the day after that, 12. Coincidently with this renewed delayed coagulability, the bleeding recurred from the finger tips, lips, and nostrils. Numerous pustules then broke out over the body, and into the pustules bleeding occurred. The time of the blood coagulability gradually increased and the bleeding became more profuse, so that about eight days after transfusion the blood showed no tendency to clot. The child was in a deplorable condition, and succumbed shortly thereafter, exsanguinated and septic. Evidently the transfusion, though it temporarily put a stop to the bleeding by adding to the infant's blood those elements in which it was deficient, did not remove the exciting cause of the hemorrhagic diathesis, and consequently after a few days the effect of the transfusion was lost.

It would seem, therefore, that we must distinguish the several varieties of hemophilia in the new born. In some the bleeding is controlled by the well known medical means; in others blood transfusion will succeed in checking the hemorrhage; while in still others this latter will be of no avail. It is the duty of the clinician to determine when blood transfusion will be of value and when it will not.

However, the good effect obtained by Crile and by Carrel should certainly stimulate further trial of this procedure in cases of hemorrhagic diathesis, knowing as we do that bleeding in cholemia usually results fatally, and that forty per cent. of the cases of hemophilia in the new-born terminate in death.

The writer has found blood transfusion to be one of the best means of preparing feeble and exsanguinated patients for major operations. It increases their resisting power immensely, thereby enabling them better to stand the shock and other effects of such operations. In three cases blood transfusion has been employed by the writer as such a preliminary step to severe operations, and in all we were deeply impressed with the good effect. The history of one of the cases will be cited as an illustration:

Charley B., two and one-half years old, was referred to the first surgical service of Mt. Sinai Hospital by Dr. Henry Heiman. Several days previously the child had swallowed a caustic fluid with the result of causing ulcerations in the gastric and pyloric mucosa. In order to feed the patient a gastroenterostomy had been done, which operation had to be followed by a jejunostomy because of leakage alongside of the tube inserted into the stomach. The feeding by the jejunostomy opening enabled us to maintain the life of the patient for a period of several months, during which he passed through an attack of measles and bronchopneumonia. At the end of several months his nutrition, which had been fairly good, commenced to fail; he became emaciated—his weight being 17 pounds—and in spite of all the efforts of the pediatrists no improvement could be effected. It was evident that unless the normal gastroenteric relations were reestablished the child would succumb from inanition, but its physical condition forbade any abdominal operation. A preliminary blood transfusion from the father was therefore made. The child's hemoglobin rose from 50 to 90 per cent. and its pulse materially improved in quality. The stomach and jejunum were freed from the abdominal wall, the fistulous part of the jejunum was excised, posterior gastroenterostomy according to the Y-method (Roux) was done, and the opening in the anterior wall of the stomach was closed, thereby reestablishing the gastroenteric circulation. The child bore the operation which lasted almost one hour extremely well; showed no shock, and made an uneventful convalesence. In two other patients the writer has had equally good results; one had a large abdominal tumor and bore an exploratory laparotomy very well; the other was exsanguinated from hematemeses arising from a gastric ulcer.

Experimentally blood transfusion preceded by bloodletting has been found to be the most effective treatment in illuminating gas poisoning. Trial has also been made of the procedure, though thus far to no avail, in enfeebled and poorly nourished states such as marasmus, in the hope that thereby a new start will be given to the patient. Negative results have likewise followed blood transfusion in pernicious anemia, leukemia, carcinoma, strychnine poisoning, and diphtheria toxemia. In tuberculosis, chronic suppurating conditions, and acute self-limited diseases, the value of blood transfusion is still undetermined.

The writer has shown to-night that the modern operation of blood transfusion is unattended with risk to the donor or the recipient; that in several diseased conditions it is of decided, yes, of life-saving value, and that in others its full worth is not yet determined. While it is not a universal panacea, it is nevertheless an important addition to our armamentarium, and its true worth will be decided only after further experimentation and clinical use.

THE ROENTGEN RAY AND THE ETIOLOGY OF CANCER.*

By WILLIAM H. DIEFFENBACH, M.D.,

NEW YORK.

We owe it to ourselves and to mankind to contribute anything which in our judgment and experience may shed light upon the etiology of cancer, concerning which the medical profession has been groping in the dark for many centuries. The writer believes that his conception of the etiology of cancer will bear the test of time and desires to explain his views by quotations from his article in the Medical Record, December 8, 1906, which the recent report of the "Imperial British Cancer Research Fund" appears to corroborate in every way.

A quick review of the various theories and observations on this subject will prepare the reader for the subsequent argument. Starting with the father of cellular pathology, Virchow emphasizes local disposition due to injuries, operations, and irritations as contributory factors in the evolution of cancer. He does not, however, explain the method of cancer cell propagation, and he affirms the factor of heredi-

*Read before the American Roentgen Ray Society December 28, 1908.

tary transmission, which all recent statistics seem to disprove.

Cohnheim's theory of defective embryonic development causing the formation of tumors and of misplaced epithelial dormant cells which undergo cancerous proliferation, is taught from the rostrum as one of the plausible explanations of the etiology of this disease. Beard (Edinburgh) has recently promulgated a theory along similar lines. He maintains that "aberrant germ cells" are produced, in what he terms "the critical period" in embryonal development, and that a tissue called trophoblast is formed from which cancer propagates. This tissue has lower vitality than normal tissue, and according to his theory can be destroyed by certain pancreatic ferments, notably trypsin.

Gaylord (Buffalo) claimed some years ago to have discovered the cause of cancer in a coccidium—*Coccidium sarcolytum*, which was said to respond to Koch's postulates, producing similar lesions, to those of the parent body from which it was derived.

This discovery has been confirmed by various investigators, denied by others, the latter claiming that the microorganisms were due to incidental contamination or were the products of degenerative tissue change. Various other organisms have from time to time been discovered in cancer tissue, including Doyen's *Micrococcus neoformans* and Schmidt's micrococcus, only to be thrown into the pathological scrap-heap after official investigation. Quite recently the lay press reported that a Buffalo physician had attributed the cause of cancer to the earthworm which deposited the infection through contact with vegetables. Vaccination has also been accused of being coincident with the increase in cancer, and the assertion has been made that abnormal cells are introduced into the circulation through the vaccine and lying dormant in the tissues become active after irritations, etc.

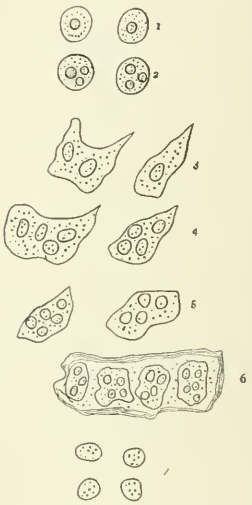
W. Rogers Williams, in his recent book, "The Natural History of Cancer" (Wm. Wood & Co., 1908,) attempts to show that cancer is a disease of alimentation and looks for the prophylaxis in the modification of nutrition, especially as regards diminution of the amount of nourishment habitually taken.

Bell (London) has similar views, and points to autointoxication and constipation as leading factors in the etiology of cancer. McConkey (*N. Y. Medical Journal*, December 19, 1908) attempts to show the relationship between the tubercle bacillus and cancer, and cites an array of interesting pathological facts.

The writer's observations were drawn to new lines owing to the following incidents in his practice, which it will repay to detail. In 1902, a patient who had been treated at various times for chronic catarrhal nephritis with coincident catarrhal prostatitis, was attacked with an acute exacerbation following a cold—his urine was bloody, contained connective tissue shreds, epithelial and granular casts, and numerous epithelia from the kidney, pelvis, urethra, prostate gland, and adnexa. Among the epithelia were a number of squamous epithelia with numerous nuclei or rather endogenous new formations (see No. 4), which to the writer looked suspiciously like squamous cancer cells (No. 5). To verify his diagnosis a specimen of the urine was sent to the well-known urinary pathologist, Dr. Louis Heitzmann, of this city, who reported the presence of an acute croupous recurrence of a chronic catarrhal nephritis with chronic catarrhal prostatitis and evidences of cancer formation in the urethra about the prostate gland. This confirmation of the writer's suspicions in regard to the multinuclear cells and the tentative diagnosis of local cancer formation received a rude but pleasant shock when the patient improved within a month's time and the urine cleared up, so that now, after six years, aside from a mild catarrhal nephritis and prostatitis, diagnosed by the presence of the renal and prostatic epithelia and a few fatty pus corpuscles, the patient is in satisfactory health.

The recovery of this patient induced the following line of investigation:

In examining the urine of pregnant women it will frequently be noted that the epithelial cells of the urinary tract upon which pressure is exerted by the developing fetus, show what have been termed "epithelia with endogenous new formations." This



Endogenous new formation in several forms of epithelia (x 500): 1, cuboidal epithelia; 2, the same, with endogenous new formations; 3, squamous epithelia; 4, the same with endogenous new formations; 5, squamous cancer epithelia; 6, cancer nest; 7, sarcoma cells.

same phenomenon is noted when tumors press upon the kidneys and bladder or when an hypertrophied prostate impinges upon the urethral mucous membrane. In severe inflammation of the genito-urinary tract, the epithelial cells found in the urine frequently have these new formations and certain squamous epithelia such as those from the urethra and bladder look exactly like a squamous cancer cell.

These abnormal cells disappear from the urine when the period of gestation is passed or when severe inflammatory conditions are ameliorated, showing conclusively that pressure and inflammatory stress are able to change the character of cell morphology. *The point we will attempt to prove, based on these observations, is that a continuous or frequently repeated irritation, inflammation, or pressure will eventually produce abnormal cell progeny and consequent abnormal cell proliferation—in other words, we will attempt to explain the genesis of the cancer cell.*

Bearing this broad assertion in mind, let us consider the following facts:

Kirke's "Standard Physiology" defines a cell as

"a nucleated mass of protoplasm of microscopic size which possesses sufficient individuality to have a life history of its own. Each cell goes through the same cycle of changes as the whole organism, though doubtless in a much shorter time. Beginning with its origin from some preexisting cell it grows, produces other cells, and finally dies." What, however, occurs when the integrity of these preexisting cells is interfered with? Do they propagate abnormal or different cells?

As we have had occasion to notice in the urinary examinations, and as has been noted in examinations of tissue after Roentgenization, the character of the cells can be changed by inflammatory stress and trauma. As demonstrated under the microscope, a simple squamous epithelium becomes so changed that it cannot be distinguished from a cancer cell by a competent pathologist.

Let us consider another phase of the subject: What changes occur in cells when through repeated traumata or inflammatory changes the trophic nerve supply of a part is interfered with or impaired or inhibited and its transmission of impulses is hindered?

We quote from Kirke's "Physiology" once more: "The morbid effects which division of the fifth nerve produces in the organs of special sense make it probable that in the normal state the fifth nerve exercises some special or trophic influence upon the nutrition of those parts; although in part the effect of the section of the nerve is only indirectly destructive by abolishing sensation, and therefore the natural safeguard which leads to the protection of parts from external injury. Thus, after a division, within a period varying from twenty-four hours to a week, the cornea begins to be opaque, then it grows completely white; a low destructive inflammatory process ensues in the conjunctiva, sclerotica, and interior parts of the eye, and within one or a few weeks the whole eye may be quite disorganized and the cornea may slough or be penetrated by a large ulcer."

Division, therefore, with absolute disappearance of trophic nerve influence is followed by ulceration of tissue. What occurs when, through repeated irritations, the trophic nerve presiding over tissue changes becomes inflamed and its nerve cells, nerve fibers, and sheaths through pressure lose their ability to preside over function? We can logically conclude that impulses inhibiting and controlling normal cell proliferation can be interfered with—that inasmuch as destruction of the trophic nerve is followed by ulceration, partial inhibition will permit changes in the supplied cells, which, if continued, will induce a new abnormal progeny of cells following the line of observation as already noted. These abnormal cells being under inadequate trophic nerve control proliferate riotously, slowly invade normal tissue, appear as tumors, and destroy surrounding tissues, themselves breaking down and ulcerating ultimately when the trophic influence is entirely lost through division or continued inflammatory changes. The fact that the great majority of cancer cases occur past middle life confirms these contentions.

Arteriosclerosis is a common and almost inevitable change occurring in advanced life; with it coincident changes in the nerve cells and fibers take place, with interference of function and conductivity.

The skin, when subject to friction and mild irritation, protects itself through the formation of keratin—this is particularly noted on the hands and feet. When through repeated trauma or irritation the peripheral nerve supply becomes impaired, the integrity of the skin is lowered and changes in cell proliferation or necrosis will be induced. This readily explains the overwhelming frequency of epithelioma of the face as compared with the protected parts of the body. The face is subject to traumata of all kinds, the prominence, especially about the nose, being particularly subject to such irritations. In the aged, when the innervation and the blood-supply are impaired through sclerotic changes, regeneration and repair of tissue such as follows in youth very promptly is either delayed or absent. The frequency of keratosis senilis in a poorly nourished skin is noticed by all observers—when the condition becomes aggravated and the trophic nerve becomes involved or injured, cancerous degeneration will be invited. The frequency with which senile warts and moles degenerate into malignant tissue requires no emphasis; it is so common an occurrence that prominent surgeons, notably W. W. Keen, have advocated surgical removal of these benign growths in order to obviate subsequent maligancy. Epithelioma and carcinoma of the cervix and uterus having old, neglected lacerations of the parts as a history are too common to require emphasis—as is the fact that married women are more subject to cancer of the genitalia than are unmarried women. These facts can all be referred to chronic inflammation or irritation of the parts and subsequent gradual abnormal cell proliferation. The remarkable increase in cancer of the stomach and intestines may in part be referred to the improved diagnostic ability of the physicians of today as compared with those of several decades ago. It may, however, not be amiss to refer to one feature of civilized life which may have some bearing on this subject. The old copper cooking utensils of our grandsires have now been largely replaced by enameled or agate ware. May it not be the fact that minute particles of this gritty, irritating enamel frequently mix with the food, and through oft repeated irritation of the alimentary tract after many years produce abnormal cells changes? The pylorus, particularly, as the gateway to the intestines is the recipient of irritations of all kinds contained in food, such as spiculæ of bone, seeds and pits of fruits; loose bristles of tooth-brushes accidentally swallowed may also be mentioned as irritants to this portion of the anatomy. Statistics show that the typical location for cancer of the stomach is at the pyloric end. Rectal cancer may be traced to incessant irritation from fissures, ulcers, and hemorrhoids. The use of coarse closet paper (newspapers) may after many years also be expected to induce abnormal cell changes in the mucous membrane of the rectum if our conclusions are correct.

Trauma of the female breast is a common occurrence, and so is coincident cancer of the breast in women. In the male, malignant tumors of the breast are rare. We have treated a case of carcinoma of the breast in a man, the etiology of which was traced to his occupation. He was a porter of hides, and the flaps of the leather struck him over the region of the site of the tumor many thousand times before the abnormal cell changes were noted. Cancer of the throat and tongue are much more common in men than in women. This is undoubtedly due to smoking, with the entailing irritation of the pipe or fumes—this irritation may go on for years before cell changes appear, and a trauma of a

mechanical nature may be requisite before the subsequent repeated irritations induce changes in cell proliferation.

In what way can the relative low percentage of cases of cancer of the throat and tongue in women be explained excepting on the above premises?

In the histories of cases examined by the writer many neoplasms were traced to irritations from decayed and diseased teeth and from repeated injuries to the mucous membranes in dental operations. Two cases of round-cell sarcoma can absolutely be traced to injuries following repeated dental operations about the molar regions. Two cases of scirrhus of the right breast were traced to the habit the women had of carrying purses inside of the corset and pinning jewelry in the same location for safe keeping whenever they left their homes. The constant trauma of these hard substances, striking the gland innumerable times, can undoubtedly be put down as a factor in the etiology of the subsequent tumor. Quite a number of breast tumors were referred to a single severe blow, thus one case reported being struck by a toy hammer in the hands of a grandchild, the tumor growing in the precise lesion induced by the trauma; another case resulted from being injured in an automobile, a piece of metal striking the exact location where the cancer subsequently developed.

Classification of three hundred cases of cancer observed by the writer at Flower Hospital and in private practice shows the following:

1. Sex: 60 per cent. women; married women in great majority.

2. Age: Great majority of patients from 50 to 65 years old.

3. General health: Patients in fairly good health, excepting in cases of long standing, when cachexia had supervened. Constipation present in a large percentage of cases. Negative history of syphilis in nearly all the cases. Gonorrhea admitted by nearly all male cases. Vaccination had been performed on all cases questioned on this point.

4. The infectiousness of cancer from contact or otherwise was not established, and the bacterial or parasitic origin of cancer receives no corroboration or encouragement from our experience.

5. Hereditary history in only 10 per cent. of the cases of cancer.

6. After persistent questioning, history of trauma preceding neoplasm in 90 per cent. of the cases. Offhand questioning often results in negative replies, but persistent and careful questions as regards habits, occupations, etc., usually elicit some kind of trauma or irritation to which the patients frequently attached no importance, but which, in the light of present knowledge, when oft repeated, are a menace to healthy cell development.

As corroborative of his observations, the writer desires to quote a résumé of the report of the "Third Imperial Cancer Research Fund," which has just been published.* "It is a record of vast amount of patient experiment and observations. The first report of the fund was published in the spring of 1904, the second a year later; so that the present volume is the outcome of more than three years' silence, during which work has been continuously conducted in the laboratories. The nature of the connection between the irritation and the disease has received much attention from the investigators acting for the fund. A wide study of cases of cancer has shown that the hypothesis of a congenital or embryonic origin of cancer is incorrect. Thus cancer of the skin of the abdomen is practically unknown in Europe, but common in Kashmir. This is not due to any special presence of embryonic germs in the skin of the abdomen of the Kashmirs, but to its irritation by wearing a charcoal oven around the waist. Again, cancer of the floor of the mouth is rare in European women, although not uncommon in men; but in India women suffer from it in high degree. The difference is due to the fact that Indian women chew betel nut and sleep with the plug in the cheek at the exact spot where cancer starts. In needle-women, melanotic sarcoma often develops in the fingers at the site of frequent puncturing by the sewing needle. Relief in the congenital origin being abandoned, the question of heredity is discussed. The most recent returns of the registrar-general show that in 1906, out of a total of 141,241 deaths of males about the age of 35, 12,695 were due to cancer, and that out of a total of 140,607 similar deaths of females, 17,671 were due to cancer. The duration of human life and the small number of descendants from each pair render a trustworthy statistical inquiry in man impossible at present. But this difficulty can be obviated in short-lived animals. In the mouse the question is in a fair way of being settled by means of breeding and in-breeding experiments on a large scale. As yet no evidence has been obtained that cancer has been increased by in-breeding, and the hypothesis of special inherited liability, although not disproved, is much weakened."

Journal of the American Medical Association, November 8, 1908

With this array of facts before us, the writer desires to review what Roentgenology has contributed to the study of the etiology of cancer.

Soon after the discovery of the Roentgen ray, pathological effects were noted from the effects of Roentgenization. These were, at the beginning, ascribed to the secondary rays, but closer investigation showed that Roentgen rays had a powerful effect not only upon the skin but upon the deeper tissues and organs as well. Kienboeck of Vienna soon pointed out that the intensity of Roentgenization depended upon the quality and quantity of the rays absorbed by the tissues through which they had passed. Depending upon this dosage and the susceptibility of the cell, the reaction was a mild or severe one. Mild Roentgenization permits regeneration of the attacked cell or group of cells—severe raying produces necrobiosis.

Holzknecht of Vienna proved that the action of the ray was not that of a cautery or irritant, but that it produced distinct degenerative processes to which certain cells were more or less susceptible. He also showed that, depending upon the amount of ray absorbed by the cells, degenerative changes were induced—the greater the Roentgenization the quicker the degeneration, and the more severe was the subsequent reactive inflammation. The milder the dose the more delayed was the degeneration (if any) and the milder the induced reaction. Thus the reaction might occur in some cases within three days, in others only after thirty to forty days. The action of the Roentgen ray may therefore be classified as follows: (1) The primary degeneration of cells. (2) The secondary inflammatory reaction, subsequent to the changes in the degenerating cells.

Our therapeutic success depends on the factor of cell degeneration in nearly all cases, although the hyperemia induced by the secondary reactive inflammation has value in many skin lesions (particu-

larly lupus vulgaris) and in the relief of neuralgia and neuritis.

The action of the Roentgen ray has been particularly studied in its relation to the skin and glandular structures.

Upon the skin we recognize two principal varieties of dermatitis, the acute and the chronic Roentgen dermatitis—the latter particularly, found in Roentgenologists. For the purpose of this essay the effect upon the skin and underlying tissues of chronic Roentgen dermatitis only will be discussed.

Holzknecht, Kienboeck, Oudin, Albers-Schoenberg, Scholtz, and many others have made exhaustive studies of the action of the Roentgen ray upon tissues, and proved conclusively that the degeneration of the rayed cells constitutes the principal mode of action of this agent. Upon the skin the epithelial elements degenerate, and the adnexa (including hair, nails, sweat, and sebaceous glands) partake of this degenerative change. Following this procedure we note the reactive inflammation and then regeneration or destruction of tissue depending upon the dose.

Chronic Roentgen dermatitis has been studied particularly by Unna of Hamburg, and his conclusions have been accepted by the majority of Roentgenologists. We desire to call attention especially to the fact that Unna mentions a case of fibrosarcoma developing from an area of chronic Roentgen dermatitis, and that his conclusions are that all parts of the skin partake of degenerative changes, that the epidermis becomes keratinous to a marked degree, atrophy takes place, and a predisposition to cancerous degeneration is noted. That epitheliomata and carcinomata have developed on the site of a Roentgen ulcer requires no detailed exploitation at this time. Cases both abroad and in the United States are fresh in our memory to keep this fact before us. The recent death of the Roentgen tube manufacturer, Mr. Bauer, at a hospital in Brooklyn, from carcinoma traced to chronic Roentgen dermatitis still lingers in our minds, and the many operations on Roentgen operators for carcinomatous degeneration of chronic Roentgen lesions are so well known as to require no emphasis.

The explanation offered by pathologists for the development of malignant cells in Roentgen ulcers or scars does not, in the opinion of the writer, cover the ground. They assume that under the "stimulating" effect of the rays these cells change their character and karyokinesis takes place under abnormal conditions. As continued Roentgenization produces obliteration of the blood-vessels from which the epithelial cells derive their nourishment, the latter, finding their supply of blood gone, seek nourishment in the surrounding tissues and invade them, thus practically becoming parasites upon healthy tissue. This hypothesis does not, in my opinion, explain the process of malignant degeneration as well as does the theory of trauma, irritation, and chronic inflammation with coincident impaired trophic nerve supply and a subsequent progeny of abnormal cells formed in a new environment.

All Roentgenologists can affirm the undoubted efficacy of the ray in epithelioma, and all observers know that chronic Roentgen dermatitis has, in numerous cases, in different parts of the world, produced cancerous degeneration of tissue. This seeming paradox can be physically explained by the fact that Roentgenization, if applied in a given dose, will be followed by degeneration of the cells attacked, and regeneration of surrounding tissue will follow. Normal tissue being less susceptible to the action of the ray, the abnormal cells will degenerate most rapidly and be replaced by healthy reactive scar tissue. If this area is not attacked too soon after the desired effect has been obtained and raying is suspended, all will be well; if, as is frequently the case, however, raying is kept up for many months and the trophic nerve supplying the parts becomes inhibited through inflammation or atrophy of surrounding tissue, the familiar aspect of the Roentgen ulcer is noted with its non-response to treatment and its frequent cancerous degeneration.

The Roentgen ray in its relation to the etiology of cancer has practically annihilated the germ theory of cancer upon which so many experiments have been made, for in none of the excised lesions of Roentgenologists or in others in whom cancerous degeneration supervened has a specific germ been found.

The experience with the Roentgen ray has also killed the bugbear of hereditary predisposition to cancer, for the Roentgenologists attacked give no special history of this kind and had, previous to their Roentgen injuries, been in robust health. Our researches must hereafter, therefore, be confined to the study of vital processes themselves and the pathological observations of the writer on the changes of epithelial cells in inflammatory states of the urinary tract, where they can be readily studied, point out a clear road for further corroborative and experimental study.

To recapitulate our conclusions:

Neoplasms are due to interference with normal cell reproduction induced through trauma, pressure, severe inflammations, or constant irritations; these factors act upon cell proliferation by producing abnormal cells which in turn, if the original irritating status is maintained, again generate cells of their own kind.

If trophic nerve impulses are not interfered with, normal conditions may supervene when the irritation or inflammation subsides.

If involvement of the trophic nerve takes place so that efferent and afferent impulses are interfered with or inhibited, riotous development of the new progeny of cells will be invited. If the trophic nerve supplying the part is severed or permanently inhibited, ulceration will supervene.

The above theory places the etiology of cancer formation upon a rational basis, and permits us to guard against its increase by prophylactic measures which readily suggest themselves.

TWO UNUSUAL CASES OF INFLUENZA-PNEUMONIA.

By ROLFE FLOYD, M.D.

NEW YORK

The following two cases of influenza-pneumonia, both occurring in private practice, seemed to me of sufficient interest to warrant putting them on record; the first, because of its extreme mildness; the second, because of the coincidence of rapid and complete consolidation with an abatement of all constitutional symptoms.

Case 1. *Very Mild Influenza-Pneumonia.*—Incomplete consolidation is almost the rule in the pneumonia that accompanies influenza in New York. In mild cases, with very slight and late-appearing signs, it is sometimes hard to determine whether the influenza is complicated by a true inflammation

of the lung parenchyma or not. Such patients are spoken of as "threatened with pneumonia" or "suffering from acute congestion of the lungs," or by some similar phrase indicative of the physician's inability to make a certain diagnosis. It is of interest to know in this connection how mild a true in-

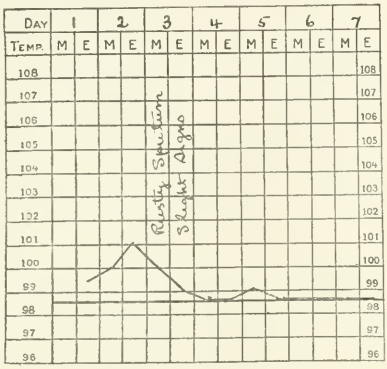


Fig. 1.—Temperature chart of Case I.

fluenza-pneumonia can be. In the following case the presence of typical rusty sputum put the diagnosis beyond question.

A man, 68 years old, came to my office February 23, 1906, suffering from a catarrhal laryngitis. He had had no chill or other marked symptom of onset, but he felt a little miserable. I saw him at his house in the evening feeling a little sick, with temperature of 99½° F. by mouth. There were no abnormal physical signs over the chest.

On the second day of his illness he was about the house, eating fairly well, somewhat hoarse from his laryngitis. Some body pains developed towards evening, but he had no chill and no pain in his chest. There were no abnormal physical signs over the lungs.

On the third day he had rested fairly, and was eating a little solid food. There were slight body pains, but he was hardly sick. He had a very infrequent cough, perhaps six times in the day, and raised typical rusty sputum each time. There was now slight comparative dullness at the base of the left lung, and in same area the breathing was a little increased in intensity and a little altered in quality. There was no change in the voice and no râles. When these symptoms and signs developed, he was sent to bed, much against his will.

On the fourth day he was very comfortable, with no pain anywhere. He ate three meals. His cough was still very infrequent, but he raised about two ounces of sputum in twenty-four hours. In the morning it was typically rusty, with some blood streaks, but in the evening became paler and more mucopurulent in character. There was distinct comparative dullness at the left base, with breathing of slightly altered quality. There was no change in the voice, and there were no râles.

On the fifth day he was no longer sick, appetite good, anxious to be out of bed. Sputum mucoid and tenacious. The dullness persisted, but the breathing was normal again.

On the sixth day he was out of bed for one hour. He raised a little rusty sputum in the morning. Dullness was persistent at the left base.

On the eleventh day the patient was well. The abnormal signs over the lungs had entirely disappeared.

Case II. *Influenza-Pneumonia With Complete Consolidation Appearing During Defervescence by Lysis.*—Man, 34 years old: Six weeks ago he had an attack of influenza, associated with severe coryza, moderate bronchitis, and a temperature of 102½° F. This attack lasted ten days. This evening, January 16, 1908, he was taken with chills, body pains, restlessness and prostration. His temperature rose to 103° F.

On the second day of the illness he was very miserable. He had hardly closed his eyes during the night. Anorexia was complete. There was no cough. There were no abnormal signs over the lungs, and no evidence of any local inflammation.

On the third day he had had no sleep at all. His face was beginning to look poisoned, and his restlessness was increasing. There were a few subcrepitant râles at both bases, more on the right side. There was no change in note, voice, or breathing.

On the fourth day he had had no sleep. Face typical of bad influenza poisoning. Restlessness extreme. Pulse not up to 100. Respiration not disturbed. Physical signs same as on the third day.

On the fifth day he felt a little better, because he got three and a half hours of sleep in the night, after taking bromide. In the evening he felt sicker again, and began to have pain in the left chest, with some cough. There was slight comparative dullness at the left base with altered vesicular breathing. A few subcrepitant râles at both bases.

On the sixth day it was reported that the night had been one of extreme restlessness, in spite of bromide. He wandered from one room to another most of the time, and could not lie still in bed at all. His mind was flighty, but he did not become actually delirious. On this day he looked pretty sick, but his temperature was only 100° F., his pulse and respiration hardly disturbed. He had no cyanosis, but a little subjective dyspnea. The pain in the side was nearly gone. He had a slight cough. There was dullness with distinct bronchial breathing and bronchial voice all over the left lower lobe. He was

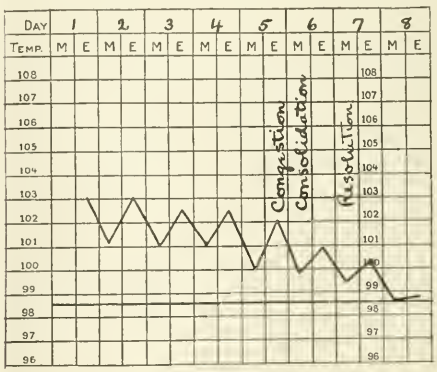

Fig. 2.—Temperature chart of Case II.

given one-sixth grain of morphine by hypodermic, and had a comparatively comfortable day, sleeping a good deal at intervals. In the evening he took a little solid food, and looked less poisoned.

On the seventh day he looked convalescent, after a good night. Air was beginning to enter the left

lower lobe, and the bronchial voice and breathing were much less distinct. Coarse râles were just beginning.

On the eighth day, convalescence and resolution were advancing rapidly.

On the ninth he was still gaining rapidly. He was taken out of bed for an hour. There was no more bronchial voice and breathing; only dullness and râles.

On the eleventh day he was out of the house.

On the thirteenth day the patient was well. No abnormal signs.

A peculiar feature of this case was the small amount of sputum raised; a little mucopus a few times, once blood-streaked, but never rusty. The lymphatics took away a large exudation very promptly.

REDUPLICATION OF THE TIBIA.*

By JOS. B. BISSELL, M.D.,
NEW YORK

I WISH to present this case to you for several reasons: Its rarity, the early age of the subject, the extensive involvement of the disease, and the complete and rapid recovery. Reduplication of bone from the periosteum and the epiphyseal centers is not rare theoretically. Practically, however, we meet with few cases showing such marked results as are found in this little baby, which I show you this evening. The extensive metastases which took place in this subject adding to the difficulty of its recovery make the case still more unique, and thus I hope worth more than a passing notice.

The patient, a boy, R. L. S., at the time of my being called to see him, was eight weeks old, weighed ten pounds three ounces, and was of healthy parentage. Mother has had seven children, two of whom were twins. This is his first illness. Nourished by modified milk from his birth.

While at the seashore, July 8, 1908, a few days before I saw him, a small abcess had appeared over the mental prominence to the right of the middle line. It was opened and healed rapidly. Following that or coincident with it the baby developed an acute attack of colitis, which subsided in about seventy-two hours. Immediately after this intestinal infection, a point of inflammation appeared at the junction of the upper and middle fourth of the right tibia anteriorly. This grew rapidly worse and developed into an abscess which was opened and the pus evacuated.

On my first visit to the patient, a new point of infection had developed over the lower portion of the tibia at its crest, and within forty-eight hours another point of infection appeared low down in the calf muscle. These were opened. As the cavity of the upper abscess seemed pretty deep, a drain was pushed through near the lower part of the popliteal space. Following that I connected the upper and lower part of the tibial area of infection, and drainage was carried through the openings.

During the following two weeks of treatment an abscess developed over the left sternoclavicular junction. Later two small abscesses developed in the periosteum of the skull posteriorly. These latter were opened and drained, and they healed without incident. The abscess at the sternoclavicular junction healed in about three weeks. In the meantime, the sinuses of the tibia were treated by free drainage, constant irrigation, and Bier's cups. On August 19, on removing some pieces of dead bone from the upper sinus, I discovered that the main portion of the bone seemed to be gently rotating in the forceps. All of the tibia from the epiphysis above to the epiphysis below, that is, the entire shaft of the bone, came away without any difficulty. Daily irrigation through the sinuses was continued, until by September 25 the openings closed. There remained an ulceration at the site of the original abscess of the leg which necessitated treatment lasting several weeks.

In order to prevent the fracture of the fibula, which did not seem to be infected, and to prevent deformity of the leg, a moulded plaster-of-Paris splint extending from the groin to below the ankle and encircling the foot was applied for support. Later on a plaster-of-Paris splint—with a window cut in it to permit local treatment—was used to support the leg, the plaster of Paris extending from the toes to the upper portion of the femur. After the lesion in the soft tissue seemed to be entirely healed the plaster of Paris was removed, and an endeavor was made to hold the leg by means of bass-wood splints. The plaster of Paris had to be omitted because of excoriation in the upper part of the thigh, due to dribbling of urine, and also to a slight superficial infection on the heel. The baby constantly injured this leg by striking it with the other foot. Therefore, as soon as the skin was healed, I put the whole leg back in plaster of Paris, making a solid split from the toes to the groin with the knee slightly flexed. As far as I could tell—examining the leg from time to time—there was a bony tibia, but, because of the fact that I had removed the entire shaft of this bone between its epiphyseal centers, I was timid in using much pressure, or in allowing free motion of the leg.

Before applying the plaster-of-Paris solid splint, on October 25, I had an *x*-ray taken of the leg. It was difficult to hold the child quiet, which is the cause of the indefinite outline to the edge of the tibia in the plate, but the solidity of the bone can be shown by contrasting the bones of the leg with those of my fingers, as shown in the *x*-ray plate.

On October 10 a new abscess appeared over the back of the skull. This was opened and drained. It healed without trouble in ten days. Later still, I removed a piece of the lower jaw of the left side that has healed rapidly and completely. The necrosed bone removed is about the size of a dime. It was obtained November 7, 1908. It is here in this bottle with the tibia. This is the last infection to date. The baby has taken nourishment constantly with very little if any difficulty. He now weighs fourteen pounds plus.

The rapid healing of the points of infection on the scalp and of the sinus at the acromioclavicular joint, as well as of the disease in the tibia, was hastened by the application of Bier's cups to the location of the trouble at each special point

46 WEST FIFTY-FIFTH STREET.

*Read before Section on Surgery, Academy of Medicine, December 4, 1908.

A Purin-free Diet in Seasickness.—Dr. A. Stanley Green writes in the *British Medical Journal*, calling attention to the possible influence of abstention from meat as a prophylactic of seasickness. He says he was always a great sufferer from seasickness until, for another reason, he put himself on a purin-free diet. Since then he has crossed the channel several times in very rough weather without a qualm.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, March 27, 1909.

GEORGE BERNARD SHAW ON THE MEDICAL PROFESSION.

MR. SHAW on one occasion greatly hurt the feelings of English medical men in general by his caricatures of physicians in the "Doctor's Dilemma," and recently in London he has hardly redeemed his reputation in the eyes of the profession by a speech delivered before the Medico-Legal Society on February 16. The subject of the address was a socialist criticism of the medical profession and the pith of the remarks was to the effect that medical men had deteriorated in position and had retrograded in earning power during the past thirty or forty years. Indeed, in the speaker's opinion, the doctor of the present day had been practically driven into the position of a private tradesman. A doctor gave his opinion and the patient asked him what he owed as boldly as one would a shopkeeper in the street. There being no systematic state organization of his profession naturally the doctor was forced by circumstances—however repugnant to his feelings—to go into the commerce of healing and to become a professional "medicine man"—a professional "healer"—who sold "cures" because that was what the public went to him for.

Owing to the acute competition in the medical profession the ordinary doctor was abjectly and humiliatingly poor, and worked harder on the whole than the member of any other profession or trade. His time was never his own, and in a certain class of practice the night bell never stopped. Furthermore doctors had always appearances to keep up and incurred a great many expenses really for the sake of their patients. Many who looked prosperous were in truth quite poor.

Mr. Shaw's remedy for this unfortunate state of affairs is to socialize the medical profession. His argument is that though poverty is no crime, it is closely akin to crime, that, at any rate, poverty is a bad thing, that the poor man is always dangerous, and that the doctor when poor is especially dangerous. Like most men he is as honest as he can afford to be, and in existing circumstances he cannot afford to be scientifically honest. The patient, too poor to pay for scientific treatment, demanded cheaper cures, the result being that the doctor had to gratify him in a way, and having no other means of livelihood he prescribed cheap cures and thereby became a swindler. According to the speaker, and allowing for all paradox and exaggeration it must be confessed that his statements are illuminated by truth, the doctor resembled in many respects a servant trained in a large charitable institution. His training was given at a hospital where were nurses, antiseptics, and so forth. He spent his student days in a building wonderfully and beautifully made with no right angles but with nicely rounded corners, and then, just like the servant, he was suddenly pitched into a poor district and had to go through life in surgically dirty clothes and do his work in surgically dirty rooms with surgically dirty people who could not afford medicines or anything. Organization, that is to say socialization of the medical profession, was the only way out of the difficulty. In order to get the maximum of hygienic influence and the greatest economy in using the skill of the profession, it was necessary to have medical men organized, so that different grades did different work, and that the mere routine should not be left to the best men to do. Such organization was altogether impossible while private practice was the rule. It could only be done if the profession was organized publicly by the State.

Mr. Shaw holds the view that organization of this nature will benefit the physician who elects to undertake private practice nearly as much as he who is in the public service. For, having the alternative of public service he will be in as independent a position as if he were a public servant; and, on the other hand, the patient will always have the choice of getting public attendance, and so he, having the alternative, will be as well off with the private doctor as he will be with the public doctor. Many men who are in a position to judge believe that in Great Britain the time is approaching with greater or less rapidity when the medical man will become the official servant of the public. Matters are in such an unsatisfactory condition from the standpoint of health and hygiene with the population in general, especially in the towns, and with the medical profession financially and otherwise, through competition and lack of unity, that steps to better the situation are loudly called for. Mr. Shaw's views may be visionary, and he may have spoken to some extent with his tongue in his cheek, but his statements are so sound in the main that they cannot but invite the earnest attention of physicians.

BLOOD COUNTS IN APPENDICITIS.

GENERAL practitioners are called more often than surgeons to treat patients with beginning appendicitis, and frequently enough they find great difficulty in deciding just when surgical interference is to be recommended. Only extended hospital experience, with opportunity to study the "pathology of the living" as disclosed on the operation table, can furnish the necessary knowledge that should guide in advising for or against operations, and, of course, such experience at present is limited to the minority of the profession. Any facts that help the general practitioner in reaching the decision in cases of appendicitis in regard to the necessity of operating are, therefore, quite welcome, especially if they are derived from extensive routine

observations made in hospitals. Such facts are presented in an interesting communication by Dr. George N. Pease in the *Annals of Surgery* for March, 1909, dealing with the value of the leucocyte and differential counts in appendicitis. The cases upon which the paper is based numbered three hundred, all of which went to operation, and in all a definite pathological diagnosis of the lesion was made. For the purpose of comparison the cases were divided into those of chronic appendicitis, of simple acute appendicitis, characterized by local inflammation without gangrene, of acute gangrenous appendicitis, of abscess formation, of appendicitis with local peritonitis, and, finally, of cases of general spreading peritonitis. The averages of the blood counts made showed that the more severe the pathological lesion the higher was the leucocyte count and the higher also was the percentage of polymorphonuclear cells in the differential count. But the mere leucocyte count proved to be a very uncertain guide in diagnosing the character of the lesion in each individual case. In many instances of severe infection the resistance of the body was so overwhelmed that very low leucocyte counts were obtained. On the other hand the polymorphonuclear count proved to be a much safer guide; practically two-thirds of the severe cases showed a count of over 85 per cent., while the great majority of cases of peritonitis were accompanied by a polymorphonuclear percentage of over ninety. The general conclusions reached from the study of the three hundred cases are, therefore, that a polynuclear count between 85 and 90 per cent. indicates the presence of a severe process; above 90, a dangerous condition with the probability of peritonitis as a complication; below 80 per cent., safety for the time being; between 80 and 85 per cent., doubt.

It seems evident, accordingly, that a careful study of the blood furnishes a very valuable guide as to the intensity of the process in and about the appendix. At the same time, however, it remains true that in each individual case no one sign or symptom should ever be looked upon as the determining factor; the blood count is only one of the diagnostic methods at our command and its value should not be judged by itself alone but in connection with all other clinical and laboratory data obtained in reference to the patient. Judicious balancing of all the information obtained is the keynote of successful diagnosis of the lesion in cases of appendicitis and, therefore, of successful treatment by medical or surgical means.

A Unique Sanitary Circular.

The communities of the effete East are wont to make merry over the freak bills introduced into and sometimes passed by the legislatures of the Western States, but if any town in any State in the Union has a Board of Health more freakish and more outrageous in its pronouncements than the Board of Health of the town of Depew in New York State it would be interesting to hear of it. We have recently been favored with a pamphlet, copyrighted by George N. Jack, M.D., entitled "Suggestions Adopted by the Depew, N. Y., Board of Health for the Prevention of Sickness, Corruption, Crime, and as an Evolutionary Aid to Humanity." The edict, or code of morality, or bunch of health maxims, or whatever it may be called, is in the form of fifty axiomatic paragraphs. We cannot undertake to reproduce them all, indeed the fear of Mr. Comstock would deter us, and we can only indicate in a general way the nature of the publication, leaving it to any curious-minded reader to write to the author for a copy, the which he will probably receive promptly unless in the meantime the postal authorities declare it unmailable. The author differs from the Psalmist and the ex-President in his estimation of the virtue of large families and regards as far from blessed the man with a full quiver. He regards it indeed as a crime for a poor man to have a large family and would restrict the number of children to four. Others have had similar views as to the advisability of the restriction of the family, but one must have lived many years and read much before meeting a public health official who would propose the author's Rousseauistic remedy for overproduction. But there are other queer pseudo-axioms in the pamphlet, which may be more discreetly noticed. No. 4 reads: "Erroneous notions regarding the sexual organs and the hereafter are the chief causes of neurasthenia, functional insanity, poverty, overbreeding, and prostitution." Correlated with this is No. 46 which affirms that "All barren uneducated people cannot be placed at the door of the physician; they prevent conception themselves. The remedy here is for science to make known the scientific fact (sic!) that we have no conscious existence after death and that those who die childless lose their only hope of continued life or perpetuation." No 9 is an epitome of the doctrine of infectious diseases: "Tuberculosis, Asiatic cholera, the plague, and smallpox are diseases of filth and over-population." An excellent hygienic maxim is No. 41 which says that "The preface (sic!) of all male children should be examined once a week." The Depew Board of Health appears to be as sound in finance as it is in morals, theology, pathology, and grammar, for it announces in this wonderful tract (axiom 20) that no man who has his money in the bank or invested in bonds ever pays taxes. We would not advise the tax-dodger to put his money in bonds on the strength of this. Genius has no show with these sanitary officers, for they say (axiom 23) that "Life is an interlocking, interchanging, magnetic reciprocation, therefore one will never rise mentally or physically much above the status of his country." We hope that the converse is true, that no citizen of our country can ever fall mentally much below the status of the writer of these atrocious "pioneer suggestions," "framed by the Depew Board of Health for the advancement of the human race."

Spitting and Sweeping.

The recent revival in this city of activity in enforcing the antispitting ordinance is justifiable so far as it goes, but like many reforms it scarcely goes far enough to be of permanent value. Spasmodic efforts seldom achieve very much for very long; they are like flames that spring up from dying embers only to be smothered in the smoke and ashes which they create. Reforms, like all other agencies of progress, must be steady and

insistent if the work they are intended to perform is to be of lasting value. In the midst of our efforts to secure ourselves and posterity against untimely disease and premature death we are strangely lax in carrying out the very first principles of what we call the modern services of sanitation. It is scarcely too much to say that a single sweep of a porter's broom upon the cement platform of a subway station sets into motion more colonies of dangerous bacteria than do the careless and disgusting persons who make themselves a public nuisance by expectorating in the very pathway of their neighbors, although it is true the porter's broom is made more of a menace because of the spitter who has supplied the germs for disposal. To minimize the evil of the spitting habit would be an offense, but to magnify it and say nothing of conditions which are far easier to control is neither just nor wise. The street cleaners come in also for their share of opprobrium, and the methods they now use are in urgent need of change. Why should one fresh from a morning bath and in the exhilaration of cleanliness and fitness for the day's work be subject to a shower of ashes and dirt within two minutes after leaving his door? Eyes, nose, mouth, and ears are filled with irritating dirt, and must perchance remain so for the greater part of the day. It is very difficult to see why the toilet of the city should not be performed at night or in the early morning hours before most people are astir. That is the logical time for the collection of garbage and ashes, the sweeping of streets, and the flushing out of gutters. The idea is not new, it has been brought up before, many times, but the old state of things continues. Our slumbers are not likely to be so much disturbed by the work of the scavengers as by the honks of the auto and the clang of flat-wheeled cars. If a heavy fine were imposed upon each and every person who violated an ordinance against unnecessarily poisoning the air we are obliged to breathe, a long step would be taken in the prevention of respiratory and kindred diseases.

Experimentally Produced Tumor.

The experimental study of tumors has of late mainly followed two directions; one of them consists of the transplantation of the tumors of animals into series of healthy individuals, the other of the many attempts to produce tumors in healthy individuals without inoculating them with other tumor cells. These latter attempts have usually met with complete failure, for the various masses of new tissue produced by the use of chemical and mechanical irritants have in the end proved to be simply inflammatory in character and usually failed to persist after the action of the irritant was discontinued. Somewhat more successful have been the numerous endeavors to imitate certain tumors by transplanting various actively growing tissues of one animal into another. One such experiment apparently crowned with unusual success is reported by Neuhäuser in the *Deutsche medizinische Wochenschrift* for February 25, 1909. This investigator utilized for his experiments the adrenal bodies of rabbits only a few days old, transplanting them into the kidneys of other rabbits. In one instance, at least, the implanted piece of adrenal tissue continued to grow in the tissues of the kidney and finally reached many times its original size. More than that, its cells seemed to have invaded the blood and lymph vessels of the host's kidney, so that actively growing areas of tumor could be seen in the vessel lumina; the borders of the new growth, too, were not sharply circumscribed, but showed numerous projections invading the surrounding tissues. Of course, the success in this case has been quite exceptional. However, even a single positive result must be looked upon as of great interest, for there are many reasons for the usual nonsuccess of such experiments. If Neuhäuser's conclusions are accepted they will furnish additional support to the Cohnheim-Ribbert inclusion theory of tumors.

News of the Week.

Sanitary Science and Public Health.—The course of lectures on this subject given at the College of Physicians and Surgeons, Columbia University, 437 West 59th Street, will be concluded during the month of April. The titles and the lecturers for the remaining dates will be as follows: April 5, Quarantine and Disinfection, Past Assistant Surgeon L. E. Cofer, United States Public Health and Marine-Hospital Service, recently Chief Quarantine Officer of the Hawaiian Islands and President of the Territorial Board of Health; April 7, Tenement House Sanitation, Mr. Robert W. de Forest, President of the Charity Organization Society, New York; April 12, Diseases of Animals Transmissible to Man, Dr. Theobald Smith, Fabyan Professor of Comparative Pathology, Harvard University; April 14, Personal Hygiene and the Hygiene of Communities (Gymnasia, Public Baths, Playgrounds, etc.), Dr. Luther Gulick, Chairman, Playground Extension Committee, Sage Foundation, New York; April 19, Industrial Hygiene and Sanitation—Factory Inspection, Dangerous Trades, Preventable Accidents, Child Labor, Mr. Frederick Ludwig Hoffman, Statistician, Prudential Insurance Company, New York; April 21, The Prevention of Alcoholism and Insanity, Dr. Frederick Peterson, Professor of Psychiatry, Columbia University; April 26, Visiting Nursing and Its Influence on the Prevention of Disease, Dr. Richard Clarke Cabot, Instructor in Clinical Medicine, Harvard University; April 28, The Influence of Education on Public Health, Mr. Homer Folks, Secretary of the State Charities Aid Association, New York. The lectures are open to the public without tickets of admission, and are given at five o'clock in the afternoon, the doors of the hall being closed at ten minutes after the hour.

Health Conditions in the Canal Zone.—The report of the Department of Sanitation for the month of January, 1909, calls attention to the low death rate of the total population under the jurisdiction of the department—22.86 per thousand. This is a considerable improvement over the rates for the same month in preceding years, which were as follows: January, 1905, 40.20 per thousand; January, 1906, 47.26; January, 1907, 35.12; January, 1908, 26.66. Among employees only the death rate per thousand is very much lower—10.98—and is also below the rates for preceding years, which were: January, 1905, 20.26 per thousand; January, 1906, 40.36; January, 1907, 25.62; January, 1908, 12.72. No case of yellow fever or smallpox occurred during the month, and the general health conditions were excellent.

Plague in China.—Sporadic cases of bubonic plague are reported in Amoy, China, by Dr. A. D.

Foster, Surgeon in charge of the American Marine Hospital at that point. He has recommended the detention and disinfection of passengers for the Philippines before they embark.

Foot and Mouth Disease.—Despatches from Kingston report that the foot and mouth disease has broken out among the cattle in Jamaica. The Government is taking drastic measures to stamp it out.

Tuberculosis Committee.—The annual report of this committee of the State Charities Aid Association of New York has just been issued. During the year from March 16, 1908, to March 16, 1909, the traveling tuberculosis exhibition was shown in nine cities. One hundred eight public meetings were held, and at these over 300,000 pieces of literature were distributed. Smaller exhibits were sent to thirty-six county fairs, 25,000 personal letters were sent throughout the State, 150,000 pieces of educational matter went out from the central office, and nearly one million pieces of such matter were distributed in various ways. Four counties are to have hospitals for advanced cases, and dispensaries have been opened in five cities. This work is all done outside of New York City.

The Otisville Sanatorium.—The New York City Department of Health calls attention to the facilities for the care of early cases of pulmonary tuberculosis, which are now available at the Municipal Sanatorium, situated at Otisville, New York. This institution has at present a little more than two hundred beds, and the number is being increased as rapidly as possible. Incipient cases and early second stage cases will be accepted. Application for admission should be made at the clinic for communicable pulmonary diseases of the Department of Health in the Borough of Manhattan, situated at 55th Street and Sixth Avenue. Physicians may send their patients directly to this clinic for examination with card or letter.

Summer Course in Chemistry.—Columbia University, New York, announces a course in chemistry to be given in the Summer School during the six weeks from July 7 to August 18, which will include the study of important organic substances of interest to medical men. The following classes of compounds will be considered: Sugars and carbohydrates, fats, amino acids and the hydrolysis of proteids, the uric acid group, alkaloids, essential oils, the artificial remedies and the bearing of their chemical constitution on their physiological function, etc. A series of eighteen lectures will accompany the course, if the attendance is sufficient to warrant it. Other courses will be given in the Summer School on elementary physiological chemistry, on the chemistry of nutrition, and on organic and sanitary analysis. Further information may be obtained from Professor J. L. R. Morgan, Columbia University, New York.

Addition to St. Luke's.—Plans have been filed with the Building Department for a nine-story addition to St. Luke's Hospital, New York, to be known as the Traverse' Pavilion. The addition will form a new wing at the east end of the hospital quadrangle. It is to be of brick with marble trimmings, harmonizing with the existing group of buildings. The first floor will contain a series of surgical operating rooms and examination rooms, and a sterilizing room. The second floor will have more examination rooms, an electrical apparatus room, and a laboratory. On the eighth floor there will be a solarium with a roof garden on top. The pavilion will be for dispensary patients, and will cost about $200,000. It is being erected as a memorial to William R. and Maria L. Travers, the parents of the donor.

Regulation of Laundries.—The passion for sterilization has extended to the laundries, and a bill has been introduced into the New York Assembly providing that all soiled clothing sent to laundries shall be contained in bags, and that these bags and their contents shall be subjected to a heat of 212° before they are opened. Some of the laundrymen have suggested going still further, and propose devising a plan by which the laundered goods may be sent back to the customer in a sealed package, having been sterilized just before it is sealed. The passage of such a bill would probably do away with most of the small Chinese laundries in the city.

Street Car Accidents.—During the month of February there occurred in New York a total of 3,508 accidents on the lines of the transportation companies within the limits of the city, according to the report of the Public Service Commission, the total number of persons injured being 2,188. Of these twenty-seven were killed, seven suffered fractured skulls, two amputated limbs, and fifteen broken limbs, while 140 others were seriously injured. For February, 1908, the total number of accidents was 3,951, and the total number of persons injured 2,157.

Dr. Wolff Freudenthal of New York was recently appointed a corresponding member of the German Laryngological Society of Berlin.

For the Employment of Epileptics.—A society has been organized in Philadelphia for the purpose of securing employment for epileptics. Dr. Matthew Wood has been elected president, and Drs. J. Madison Taylor, Thomas J. Mays, P. E. Bland, John H. W. Rhein and William M. Capp, directors.

Colonies for Epileptics.—The Illinois Legislature is considering at present the appropriation of $803,000 for the establishment of three special colonies for epileptics, one at Kankakee, one at Anna, and a third for feeble-minded children at Lincoln.

Hospital Quarantined.—Two cases of scarlet fever developing among the patients of the Presbyterian Hospital have made it necessary to place the institution under quarantine.

Diphtheria in University.—Three students at the University of Pennsylvania were recently found to be suffering from diphtheria and were removed to the Municipal Hospital.

Red Cross Stamp.—The success of the sale of the Red Cross Christmas stamp last winter has determined its continuance as a means of raising money for the tuberculosis work, and a public competition to provide a design has been announced. Prizes will be offered for the most suitable designs submitted.

No "Eye Specialists."—The Optometrical Society of the State of New York has issued notices that failure to use the title "optometrist" by the opticians who have registered under the new law will be regarded as a cause for expulsion. This action is designed to put an end to the use of such titles as "eye specialist" and "optical expert" on business cards and signs. The society is also giving attention to the use of the title "doctor," which

is assumed by some opticians who have never received a doctor's degree.

One Hundred Ten Years Old.—Mrs. Mary West, of Chatsworth, Ill., celebrated, on March 19, what was said to be her 110th birthday. She is still able to take an active interest in every-day affairs.

Nitrite of Amyl in Hemoptysis.—Dr. Thomas R. Evans, of El Paso, Texas, writes that the profession as a whole is not fully aware of the power of nitrite of amylin arresting hemoptysis. He has recently used it most successfully in two alarming cases in young men.

St. Francis' Hospital.—The report of St. Francis' Hospital, on East 142d Street, New York, shows that 2,500 patients were treated during the past year. The total number of deaths in the institution during the year was 192, but of these eighty-six entered the hospital in a moribund condition. With these latter deducted, the death rate would be only 4.2 per cent. The surgical cases treated numbered 909.

Transfer of Insane Patients.—Because of the overcrowding of the King's Park State Hospital for the Insane, the State Lunacy Commission recently ordered the transfer of 150 patients to other institutions. Of these 100 were sent to the Binghampton State Hospital, and the remainder to the Willard State Hospital. The insane hospitals in the lower part of the State are taxed to their full capacity.

Wholesale Vaccination.—Twenty-four hundred patients, attendants and physicians at the Illinois Central Insane Asylum were vaccinated in two days recently by the order of the Superintendent, following the discovery that one of the new patients at the asylum was suffering from smallpox.

Scientific Dietist, Philippine Service.—The United States Civil Service Commission announces an examination on April 14, 1909, to secure eligibles to fill a vacancy in the position of scientific dietist, at $900 per annum, for duty in the Philippines, and vacancies requiring similar qualifications as they may occur there. Board and quarters are furnished to the occupant of this position. The examination will be based on a thesis to be submitted with the application, on a subject relating to dietetics, 25 points, and on experience, 75 points. Candidates should apply to the United States Civil Service Commission, Washington, D. C., for application Forms 2 and 375.

Southwark Medical Society of Philadelphia.—At a stated meeting of this society, held on March 18, the evening was devoted to a symposium on pneumonia. Dr. Augustus A. Eshner discussed "The Etiology and Symptomatology from the Viewpoint of To-day," Dr. Julius L. Salinger "The Diagnosis and Complications of Pneumonia," and Dr. L. N. Boston "The Prognosis and Treatment of the Disease and Its Complications."

The Iowa State Medical Society will hold its annual convention in Dubuque on May 19, 20, and 21. The convention promises to be one of the largest in the history of the society, between five and six hundred physicians from various parts of the State having signified their intention to be present. On May 18 the State Society of Iowa Medical Women will, as is customary, hold their annual meeting at the same place.

Obituary Notes.—Dr. Henry De Lacey Sherwood of Jersey City, N. J., died at his home on March 16 of a complication of diseases, aged 48 years. Dr. Sherwood was graduated from the College of Physicians and Surgeons, New York, in 1882.

Dr. Dillon Brown of New York died at his home on March 16, after a year's illness, aged 49 years. Dr. Brown was graduated from the Harvard Medical School in 1885. He was resident physician at the New York Foundling Asylum during a part of the time when the late Dr. O'Dwyer was perfecting his method of intubation of the larynx, and became himself one of the pioneer intubationists, his skill in performing this operation bringing him a large pediatric practice when he was still quite a young man. He was for some years house physician at the Netherland and Savoy Hotels, New York, and consulting physician to the Red Cross Hospital.

Dr. Hamilton Dixey Wey of Elmira, N. Y., died on March 16, at Callao, Peru, where he had gone on a trip for his health. Dr. Wey was graduated from the College of Physicians and Surgeons, New York, in 1878. He was a member of the American Medical Association of the Elmira Academy of Medicine and of the New York State Medical Society, of which he was a former president. He was also consulting physician to the Arnot-Ogden Memorial Hospital, health officer of Elmira, and at one time physician to the New York State Reformatory.

Dr. Joseph Schmittle, one of the most highly esteemed practitioners of New Orleans, La., died at his home of disease of the pancreas on March 5, aged 80 years. Dr. Schmittle, who was of German birth, was graduated from the New Orleans School of Medicine in 1862, and since that time had practised continuously in New Orleans, serving for over thirty years as attending physician to the German Orphan Asylum and Fink Home of that city. He was a member of the Louisiana State Medical Society, and an honorary member of the Orleans Parish Medical Society.

Dr. Henry Isaac Jones of Oakland, Cal., died at his home on March 7 from disease of the liver at the age of 64 years. Dr. Jones had received degrees from the University of Edinburgh (1866), the University of Glasgow, and Western Reserve University, Cleveland, Ohio (1884). During the Civil War he served in the Confederate Navy, and was at one time a surgeon in the British service in India. He was a member of the Medical Society of the State of California.

Dr. James H. Hamilton of Richford, Vt., died at his home on March 13, aged 73 years. Dr. Hamilton, who was graduated from the Castleton Medical School, Vermont, was for many years secretary of the Vermont Board of Health, and at one time a member of the Vermont Legislature.

Dr. Frederick W. Sparling of Seattle, Wash., died at his home on March 1, aged 83 years. He was graduated from the University of Victoria, Coburg, Ontario, in 1854, served as major and surgeon of volunteers during the Civil War, and later as assistant surgeon in the United States Army. In 1880 he was placed in charge of the census of the State of Washington, and was later appointed inspector of immigration.

Dr. Milton Sawyer Woodman, of West Lebanon, N. H., died on February 27 at the age of 58 years. Dr. Woodman was a graduate of the Dartmouth Medical College in 1889, a member of the

New Hampshire State Medical Society, the New Hampshire Surgical Society, the New Hampshire Antituberculosis Society, and the New York and New England Railway Surgeons' Association.

Dr. IRA A. SHIRMER, a native of Bethlehem, Pa., and a major in the United States Army, died on March 12, in the Philippines. Dr. Shirmer was a graduate of Lehigh University and of the Medical Department of the University of Pennsylvania.

Dr. WILLIAM BULLARD CUTLER of Boston, Mass., died suddenly on March 5, aged 62 years. Dr. Cutler was a graduate of Yale University and of the Harvard Medical School, receiving the degree of M.D., in 1872.

Correspondence.

SOME OF THE WORK ACCOMPLISHED IN FORMER DAYS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—As one of the early subscribers and contributors to the MEDICAL RECORD, I read with much interest the 2000th weekly issue in which some of the achievements of your journal in the interest of the medical profession are recounted. Since your modesty has led you to omit mention of other achievements outside of its function as an organ for the transmission of knowledge to its readers, I would ask permission to mention some of these of which I happen to have personal knowledge.

By referring to your files you may note that in 1884 there was considerable agitation in this city and country on the subject of Antisepsis in Midwifery. A characteristically brilliant paper on this subject had been read by the late eminent teacher, Dr. T. Gaillard Thomas, advocating the idea that "every woman who passes through labor shall be managed with the same antiseptic measures as one who is subjected to a capital operation." (*New York Medical Journal*, January 5, 1884.) Guided by clinical observation, I wrote several papers opposing active antisepsis after normal labor. I seemed "to stand alone and single-handed in opposition to this universal application of prophylactic antiseptic injections." The MEDICAL RECORD adopted the same view and offered its cooperation in this unpromising agitation. During the two weeks intervening between the reading of the paper and its discussion at a special meeting of the Academy, I made several arguments in Society discussions and in papers in the RECORD against this needless meddling with the normal vaginal canal, and the RECORD published in a six-column editorial a strong argument from the surgical standpoint, emphasizing the fact that "disturbance of healing wounds by injections had been shown in Billroth's tongue excisions to be unsurgical and that a three per cent. carbolic solution was not a real germicide; therefore these prophylactic injections were not only worthless but harmful, and their abolition would prevent much discomfort, pain and danger to puerperal women." How valuable this courageous position of the RECORD proved to be was made evident by the discussion of Dr. Thomas' paper. The prominent obstetricians who participated in it unanimously approved of prophylactic vaginal injections, except Dr. Fordyce Barker, the president. In closing the discussion Dr. Thomas displayed the spirit of the true physician by frankly avowing (*New York Medical Journal*, Feb. 16, 1884), "the arguments which have been used against this practice have had great weight with me. I confess I feel less firm in my convictions upon this point, and in future I shall examine the question carefully before I determine others to adhere to it. You may ask, why this change of opinion? I answer, I strive to mend the faults of yesterday with the wisdom of to-day." I am confident that without the influential aid of the MEDICAL RECORD the abolition of this pernicious practice which actually did follow would not have been so rapidly and completely accomplished. Those who practise in these advanced times may not realize what this sudden change of front of the foremost teacher in obstetrics meant in the saving of distress and of life. The statistics which I cited in one of my arguments from the Lying-in hospitals of Europe demonstrate the difference in the mortality with and without vaginal injections.

Another incident demonstrating the weight of influence carried by the MEDICAL RECORD was its espousal of the cause of Joseph Hoffman, who, in 1895, was attracting great crowds to his concerts by reason of his being regarded as a "musical prodigy." The child fell ill under the enormous strain to which he was subjected. Being placed under my professional care his father was advised that his absolute withdrawal from the stage was demanded to save him from physical wreck. My advice was heeded. But the manager, recognizing the great financial loss resulting from the withdrawal, "moved heaven and earth" to prevent it. His agents importuned me to modify my orders and the musical people beset me with prayers and threats to save this "genius." The newspapers were enlisted in this agitation, and every night a large number of reporters awaited my return from the patient to obtain information of his condition. A prominent medical journal had espoused the cause of the manager, and a commission, consisting of an eminent neurologist, prominent physiologist, and a surgeon convened with my consent at Dr. Sayre's office to discuss the feasibility of my modifying the interdiction. This commission decided against my view. In this dilemma, realizing my duty to the patient, I appealed to the genial editor of the RECORD for counsel. He upheld my view, and voluntarily published an editorial setting forth the true status of this matter so clearly that all agitation ceased. Thus the RECORD aided materially in saving to art a child, who was at that time regarded as a second Mozart.

Another incident in which the powerful influence of the RECORD (obtained solely by its fearless advocacy of the right) moulded public opinion, was its earnest propaganda for public baths. Its able editorials were used before legislative committees with good effect. The law making the construction of public cleansing baths mandatory, which was the consummation of my fondest hopes, had been carried successfully through the Legislature under the skilful management of the Hon. Goodwin Brown, and the Mayor appointed a bath committee to prepare for its enforcement. When this committee, through misunderstanding of a clause in the "Bath Act," reported unfavorably to the Mayor and thus frustrated the labor and effort of ten years, I sought the aid of the MEDICAL RECORD to demonstrate the erroneous construction of the act by the committee. A scathing editorial appeared in your journal (May 8, 1897), asserting boldly, "the Mayor's committee has succeeded by its own blunders in delaying the construction of public baths and in arousing needless but just antagonism against the unlawful use of Tompkins Square for public bath purposes." I had offered a resolution before the Academy of Medicine asking the appointment of a committee to urge upon the Mayor to execute the mandatory bath act, and this resolution was to be discussed at a second meeting. On the day of the appearance of the RECORD editorial, my genial friend, the late Health Commissioner Dr. Fowler, telephoned me that if I shared the view of that editorial he would advise me to call at his office and have the Board's attorney convince me of my error, before I used this erroneous idea in my forthcoming argument before the Academy. When I responded to Dr. Fowler's invitation the attorney directed my attention to the marginal index of the act, "Public Baths in Public Parks," to prove that the Mayor's committee had been correct in its report. My suggestion to the attorney to read the act itself resulted in his discovery that the marginal note was incorrect and misleading. Thus the mistaken attitude of the Mayor's committee and of the Board of Health, which would surely have wrecked this beneficent enterprise at a critical moment, was rectified by this timely editorial. The latter had another important effect. When our committee (which, by the way, was not appointed without influential opposition) appeared before the Mayor, we found that he had read the editorial which had fortunately been reproduced in the *Herald*. The Academy committee's presentation of the "resolution urging the Mayor to build the baths" was met pleasantly by this official with the reply: "All right, I have discovered that my committee was mistaken, and I have selected a lot in Rivington Street for the first bath." Thus the most salutary hygienic movement of recent years received from the MEDICAL RECORD an impetus which has constantly gathered force, as is evidenced by the present favorable attitude of the city authorities. In 1900 I had succeeded in having an appropriation of $25,000 passed by the Board of Aldermen for "an experimental bath." This was done because I could not convince the authorities that the working people would use these baths. The Mayor did not "approve" this resolution. Contrast this incident with the report of President Ahearn of this Borough, stating that last year 7,000,000 baths were given free in this city and the fact that new baths are constantly planned or constructed now. It surely redounds to the credit of a journal to have borne an influential share in such an achievement for the welfare of mankind.

51 W. 70TH STREET SIMON BARUCH, M.D.

OUR LONDON LETTER.

(From our Regular Correspondent.)

THE POLYCLINIC—POST-GRADUATE TEACHING—PERNICIOUS ANEMIA—LETTSOMIAN LECTURES—RADIUM—WEATHER—CEREBRO-SPINAL MENINGITIS—OBITUARY.

LONDON, March 5, 1909.

THE Polyclinic has survived, at any rate for the present, the serious financial crisis which I mentioned in my letter of January 1 as threatening its existence. At the annual general meeting on Monday the report gave particulars which show how grave was this crisis and how the college has passed through it. Lord Iveagh presented £200 to be used for the reduction of the mortgage debt, but even then the outlook was so unsatisfactory that closure of the institution stared the supporters in the face. This has been avoided, mainly through the generosity of Sir Jonathan Hutchinson, who offered to forego the interest on the mortgage, approximately £220, for two years, and in addition to give the Council £100 for each of those two years. Besides this he liquidated the debt of £100 on last year's working. This has prevented closure and increased subscriptions, having been promised by many members, the valuable post-graduate instruction will go on. The chairman, Dr. C. T. Williams, remarked that they had come out of the crisis very well. There were other very good rival schools, besides which the general hospitals had begun post-graduate courses, and they each had staff and materials. On the other hand, this college could bring materials from all London and make not only one, but twenty hospitals, contribute. They had also lecturers from all the hospitals, both in London and the provinces, and provided the best teaching from the whole United Kingdom.

Their laboratory was being extended and its work was most valuable, not only for its excellent teaching, but on account of the specimens analyzed and the reports made on them, from which some income was derived. The college had joined the London Post-Graduate Association.

In connection with the foregoing I may mention one of the rivals, that which has for its home the Seamen's Hospital, and calls itself the London School of Clinical Medicine. The first annual dinner took place on the 19th inst., when the chairman of the hospital gave some historical details of the society with which the school is connected. Sir William Bennett, in responding to the toast of the evening, ascribed the happy idea of forming the school to Dr. Guthrie Rankin, who was struck by material in the hospitals south of the Thames, to all of which were attached men well qualified to undertake post-graduate teaching, and many practitioners in the neighborhood who would be glad of the opportunity of keeping in touch with every advance in medical knowledge. He went on to say that those who brought the scheme to completion were well aware of the other similar institutions and had no idea of rivalry. They wanted to add to the facilities for post-graduate instruction in London, which was much behind other capitals in this respect. They had now been at work three years and about 300 persons had passed through its courses. Dr. Guthrie Rankin next spoke and insisted that this school was no rival, but an important addition to the other institutions. Lord Ridley, on behalf of the guests, recognized the desire of doctors to treat their patients in the best possible way and consequently the value of an institution which helped them to keep in contact with the advances in their science. Sir William S. Church declared that it was now necessary for many things to be learned after a man had received his diploma licensing him to practice. To attain a full knowledge of his profession he must go on learning and these schools would give him the greatest assistance.

The Medical Society of London had two papers before it on the 22d ult. relating to pernicious anemia. They dealt respectively with pathological and clinical considerations. Mr. Leonard Dudgeon stated the results of investigations he had carried on in reference to some pathological points. In two papers received by the Royal Society he had shown that autohemolysis did not occur even when the immune serum was complemented, and further that immune serum failed to hemolyze normal red corpuscles. Immune serum from pernicious anemia was less potent in agglutinating normal red cells than the serum of other diseases. Mr. Dudgeon found no evidence that autoinfection by streptococci and the resulting autointoxication had any relation to the pathology of pernicious anemia.

The clinical aspects were the subject treated by Dr. H. S. French, who said that in patients ill enough for admission to hospital there was almost always an evening rise of temperature to between 99° and 100°, but any pyrexia above 101° was very unusual in the absence of some intercurrent disease. Further, there was little tendency to subnormal morning temperatures if the records were taken at 10 A.M. and 6 P.M. This type of temperature seems unlike that met with in chronic cardiac disease on the one side and chronic sepsis on the other, and Dr. French did not fail to point out the differences. He is of opinion that pernicious anemia as we know it is really a late stage of a malady which may be much commoner than we suppose, running a subacute or chronic course, in some cases perhaps spontaneously recovering and in others becoming acute. If diagnosed earlier, some cases might possibly be cured. It is now recognized earlier than it used to be. Early recognition of phthisis has been achieved and perhaps we may hope for as much in pernicious anemia. In cases treated by arsenic pigmentation in the mouth exactly like that seen in Addison's disease might be met with. Moreover, the spleen could be felt in about a third of the cases really enlarged. Nerve symptoms are not at all uncommon in the disease. It would seem that these several points may all be of importance and a careful study of them and others lead to earlier recognition.

In his third Lettsomian lecture Dr. Martin took up the subject of treatment of functional stomach affections. He put rest in a most important place—rest for the organ, rest for the body. In mild cases after meals, in others complete rest in bed. In hyperchlorhydria he also resorted to alkalies, preferably carbonate of soda, 15 to 20 grains an hour after meals. Sedatives, as hydrocyanic acid and morphine, could be added. He also named extract of cannabis indica and carbolic acid as sedative. In very severe cases lavage once daily for a week was beneficial. In deficiency of secretion, rest in bed was the first essential remedy, and should be insisted on for a period of five or six weeks. Without this nothing was curative. A milk diet at first, carefully graduating the return to ordinary diet. The lecturer seemed doubtful whether any drugs really increased secretion, but admitted that carbonate of sodium would stimulate it, as also would nitrohydrochloric acid with nux vomica or strychnine. When drugs seemed useless lavage daily for a fortnight, then at longer intervals, using two pints of water with two drams each of sodium carb. and sodium chloride. The best time for lavage was at bed time. Lavage appears to aid by relieving the stomach of retained food and also by stimulating the membrane to secrete. Of foods which seem to stimulate secretion, carbohydrates, proteids, and meat extracts were admitted, but fat was stated to have no such action. In dilatation the foregoing treatment, with lavage and strychnine, was often beneficial, as was massage of the stomach from left to right. The lecturer had not found electricity useful in these cases. In nervous dyspepsia regulating the diet and mode of life and giving alkalies with strychnine was often successful. Sometimes bromide of potassium or valerian might be better or useful, in addition, but in such cases intolerance of drugs was not seldom to be reckoned with. Each case must be treated for itself and each considered on its merits. Even bed, diet, and massage might aggravate the symptoms of one person and cure another. Change of environment and open air and exercise were generally useful. Vomiting and flatulence were often cured by lavage, but this was not always necessary. Reflex symptoms demanded rest more than stomach symptoms. A course of a few weeks' appropriate treatment was not enough in pronounced cases. Two or three years of regulated diet and mode of life was necessary for a permanent cure.

Sir W. Ramsay, F.R.S., K.C.B., has accepted the office of consulting chemist to the British Radium Corporation (Limited).

The Radium Institute is making good progress in its arrangements. The King has become a patron. It is decided to restrict medical treatment at the Institute to the use of radium and radioactive substances—excluding *x*-rays, electricity, etc., for which there is full provision in London. The poor will be treated gratuitously, but others will be required to pay fees.

The weather has been very severe all the week. Snowstorms and cold winds have prevailed. We learn that you have also suffered, that the same conditions have interfered with your President's inauguration that have delayed our King's journey to Biarritz.

The report of the Opium Commission was issued yesterday, as to the use of the drug in the Straits Settlements and Malay States. They state that the majority of smokers are moderate, and excessive indulgence only occurs in isolated cases. They find that the evils arising from the use of opium have not increased during the last ten years. They recommend the abolition of the present system of farming the revenue and the substitution of a government monopoly with strict supervision of the shops and the prohibition of women entering licensed premises.

Epidemic cerebrospinal meningitis is made compulsorily notifiable for a further period of twelve months from the 13th prox.

Dr. Peter Horrocks, obstetric physician to Guy's Hospital, died on the 28th of February at the age of fifty-six. He was M.D. Lond. 1878. At the M.B. exam. he had taken honors and the gold medal. In one course he took the M.R.C.P. Lond. and was elected Fellow in 1889. He had in the meantime taken the science degree at Victoria Univ., having been an Owen's College student before entering Guy's. When he reached the Guy's staff he speedily attained a good position as consultant. He has served the Obstetrical Society as president and been a Fellow of several other societies. Has also been examiner at the University and held other positions. He contributed to the *Obstet. Trans.*, to *Guy's Hospital Rep.*, and other journals. At the Hunterian Society he gave the oration in 1878. At one time he was on the staff of the Hospital for Paralysis and Epilepsy.

The name of Dr. Thomas Carlyle Parkinson has to be added to the long list of medical men who have fallen victims to their zealous professional work. An Australian by birth, he studied at the University of Sydney, distinguishing himself at every stage and taking his M.D. there in 1906. He came to England and worked at the Lister Institute. This body placed at his disposal a laboratory at Elstree, in which he could investigate plague for the Indian Commission. While working at this he became infected and fell a victim to medical science, dying on February 4.

Surgeon-Major William Niven, M.D., has died at Hastings, where he lived the last three or four years, in his eighty-fourth year. He took M.D. St. Andrew's in 1852 and entered the Indian Medical Service. He served in the Persian war, 1856-1857, and had the medal and clasp awarded. Later he was medical superintendent of the Bombay Government lunatic asylum. He retired in 1881.

Lieutenant-Colonel John A. Ambrose, R.A.M.C., died suddenly on February 27 in his sixty-eighth year. He took M.D., R. U. I. in 1863 and entered the Indian Medical Service. He contributed to the *Indian Medical Gazette* papers on ipecorcuanha in dysentery, on cholera, and on the health of the children of soldiers in India.

Lieutenant-Colonel J. F. Tuohy, whose death is announced, joined the Indian Medical Service in 1879 and served in the Afghan war of 1880-1881, for which he received the medal. He was on the staff of the Lieutenant-Governor of the Northwestern Province and civil surgeon at Agra, being principal of the Agra Medical School, of the Lady Dufferin Hospital and Medical School for Women at Agra.

OUR LETTER FROM ROME.

(From our Regular Correspondent.)

ROME, March 5.

As was foreshadowed in a former letter, one of those I will not say crises in the Pope's health, which would certainly be going too far—but one of those periods in which His Holiness is not as well as usual is at hand. It was pointed out that the Pope was well advanced in years and besides being subject, like ordinary mortals, to various maladies, had a uric acid diathesis to contend with. In short, he is at present grippé, and has been obliged to give up holding audiences, and functions that had been fixed to take place have been countermanded. Professor Marchiafava, his physician, and the doctors of his entourage assure us that he is as well as circumstances admit, or as could be expected, and they naturally feel no anxiety at all with reference to his condition—and there is no violation of professional secrecy herein. The Pope is seventy-four years of age and of rather strong physique, takes plenty of exercise walking in the spacious gardens and grounds at the Vatican, sleeps well, usually having a good appetite, but, like all persons of his diathesis, is obliged to be moderate and careful in his diet, which is always of the simplest. The real truth is that the Pope is just now getting the common lot and going through a very mild attack of grip, and his doctors, with that precaution exercised by those attending royal personages, have prescribed rest and the usual remedies in affections of this kind where there is also some fever. Such are the proper ones to exhibit regardless of any diathesis and a heart none too strong. Practitioners will observe that when grip attacks a paralytic subject, or one with cerebral softening, it is quickest cured by ignoring entirely the constitutional disease and treating the grippal syndrome absolutely per se, interrupting for the time being all other treatment. At the Vatican they say the Pope is easily affected by cold and subject to catarrhal attacks. As the building is so vast and not well heated, the drafts and currents of cold air in the corridors and chapels might be responsible for them, especially in one of his age and diminished resistance. It will be remembered that but a few weeks ago he had an arthritic attack. Although this present trouble may be nothing serious, yet the repetition of attacks, and the knowledge of how easily a very mild grip may suddenly take a turn for the worse in such cases, must necessarily cause some anxiety. The Pope, nevertheless, received yesterday Cardinal Merry del Val and, as he is much better to-day, will probably soon retake his accustomed work and audiences and will have completely conquered what will probably be characterized as a passing malaise without consequence, but what was really an attack of influenza grafted onto a diathesis of which arteriosclerosis is usually an appanage.

Progress of Medical Science.

Boston Medical and Surgical Journal, March 11, 1909.

The Medical Treatment of Malignant Disease.—G. W. Gay says that the consensus of opinion now is that in many, if not most, instances malignant disease is in its incipiency a local affection, and that if it be thoroughly removed at that time a permanent recovery may reasonably be expected. We do not know how long this incipient stage lasts and are not able to get hold of the patients early enough to decide the matter by operation. Given a case of inoperable or post-operative malignant disease, what shall we do? Some discreet person should be told the true facts of the case, but generally it is not wise to tell the patient. We should rather dwell on the favorable aspects of the case and encourage the hopes of the patient. Our fight may be a losing one, but it should be carried to the end with vigor and discretion. For some years the author has given this class of patients, both before and after operation, compound iodine tincture with or without bromide of arsenic, and these remedies have been continued over long periods of time. He instances several cases in which this therapy seemed to prolong life to a considerable degree. He considers that the Coley treatment with the mixed toxins of erysipelas and bacillus prodigiosus has not received the attention its merits would seem to justify. He extols the benefits of the *x*-ray and radium bromide. We should not turn the cure of hopeless cases over to charlatans. The highest degree of conscientious personal service should be rendered to the class of patients under consideration. As the end approaches opium alone can furnish relief.

Early Treatment of Some Epitheliomas by Pure Radium Salts.—F. H. Williams reproduces the table given out by him last June, showing a cure in 56 out of 69 cases of various epitheliomas. He says that 50 milligrams of pure radium bromide are desirable. Many of those using radium use too small a quantity and too weak a quality to make the remedy efficient. The radium should be placed on a capsule covered with lead except at one side, which is at the end of a long handle as a protection to the physician. The capsule, over which a clean rubber cot for each patient has been drawn for purposes of cleanliness, should then be passed slowly over the area to be heated or held over the special place for one-half up to four minutes. The exposure should be made from one to three times a week, less often after healing has begun. The remedy must be used with sufficient daring to obtain results, but with care to avoid harm.

New York Medical Journal, March 13, 1909.

The Urine in the Diseases of Infancy.—J. L. Morse bases his observations on the results of examining the urine in 667 cases of various maladies. Putting aside, he

says, the diseases of the gastrointestinal tract, albumin and casts are more often found in pneumonia and meningitis than in other acute diseases in infancy. It does not corroborate the statements of Cassel and Simmonds as to the importance of otitis media in the etiology of nephritis in infancy, nor those of many Italian and French authors as to the frequency of renal complications in eczema. It shows that the kidneys are not, as a rule, affected in the diseases of nutrition, although in scurvy and severe anemia the urine may show the evidences of the hemorrhagic tendency characteristic of these diseases. It also shows that affections of the kidneys secondary to other diseases in infancy do not usually produce edema, and conversely that edema in infancy is usually due to some other cause than disease of the kidneys. The study of these cases seems to justify the conclusions that the presence of albumin and casts in the urine in the acute diseases of infancy is the manifestation of an unusual degree of toxemia and is, to a slight extent, of bad prognostic import. This conclusion is justified only in a very general way, however, as many infants showing albuminuria and casts recovered and many others in which the urine was normal did not. There was nothing about these cases to show that the renal condition had any direct influence on the fatal outcome. It was merely an index of the toxemia. So few pathological examinations were made that no statement is justified as to the pathological changes in the kidneys. It seems fair to assume from the changes in the urine, however, that in the vast majority of cases the pathological condition did not go beyond an acute degenerative nephritis, and that a definite parenchymatous or interstitial nephritis was very uncommon. It seems evident from the study of these cases that febrile albuminuria and acute degenerative nephritis occur in the same conditions and at least as frequently in infancy as in childhood and adult life.

Greek for Physicians.—C. W. Super exploits the advantages of a knowledge of Greek to medical men, and advises that where it is possible the beginner should take up modern Greek instead of the classics. Several physicians could form a class and thus assist each other by conference. Concerning the language as a whole, the author says that, taken all in all, classical Greek is probably the most perfect medium for the accurate expression of thought that has ever been devised by the human intellect. It is of advantage to physicians in that it not only enables them to understand the nomenclature of their own calling, but it is an avenue to general culture they cannot afford to neglect.

Successful Medical Treatment of Appendicitis.—E. Palier quotes the statistics of Robin, wherein he reports the medical treatment of 168 cases of appendicitis without a single death. He then gives clinical histories of two cases, both young women, who recovered under medical treatment. The diagnosis in one case seems to the abstractor hardly reliable, in that a vague mass in the appendix region was probably a fecal or mumous mass, for there were but slight fever symptoms and no signs of sepsis. The main point relied on in the "medical" treatment is high intestinal irrigation. The water must be warm and alkaline. Diet during the period of observation must be milk, eggs, and vegetables, no meats for some time afterward as well. Meats enhance the virulence of the colon bacilli and the general toxicity of the alimentary canal. The author takes the position that it is criminal to operate before rational medical treatment has been tried and has failed, excepting those cases, of course, where delay appears to be dangerous, and an immediate operation seems to be urgent, when, for instance, the onset is accompanied by alarming symptoms, or there is an abscess formation. If the physician, however, sees the case early and institutes the proper treatment, he will have to refer to the surgeon only cases of the first category, and will be able to avoid many complications of appendicitis. He adds that it is owing to the fact that up to recently the physician had had very little knowledge of the alimentary canal that the surgeon has shown in it such great activity.

Climate for Consumptives.—E. Everett reminds us that there are many kinds of fresh air and that each of them has a different value for different types of the disease or for the different general physical conditions of the patients. There is warm fresh air and cold fresh air; dry fresh air and moist fresh air; clean fresh air and dust-laden fresh air; fresh air of great altitudes and fresh air of the valleys; fresh air that is quiet or still most of the time, and fresh air that is blown about in gales much of the time. Most of these conditions may be helpful to some patients and positively harmful to others; a tuberculous patient may do well in some of these conditions and lose ground in others. The United States offers practically all varieties of climate. The warm, dry air of the desert though relaxing is not enervating. Patients whose condition has become low through sickness preceding tuberculosis, for instance, pneumonia, or by overwork or nervous strain, usually respond very quickly in this warm, dry, pure fresh air. It is no hardship to live out of doors for practically the entire twenty-four hours. The greatest effort required, beyond the ordinary requirements of life, is to keep out the sunshine—to keep moving into the shade. It is possible to get the maximum of fresh air with the minimum of effort or resistance to nature. During the summer months patients should go elsewhere, as the heat in these regions is often unbearable. There are others who do better in the cold pine air of the mountainous regions. For patients whose strength, weight, and vitality have not been considerably reduced, living under these conditions is possible without injury and often with positive benefit. Incipient cases, where the disease has been detected before great inroads have been made on the resisting power or cases of long standing, where the conditions of the patient as regards weight and strength have been raised up to or beyond normal in milder climates, are often completely arrested if not positively cured under these climatic conditions. But the physical and mental condition of the patient must be equal or superior to such rigorous treatment or positive injury is the result. For patients who are most reduced in weight, strength, and vitality severe cold climates are frequently harmful and occasionally fatal. They should be avoided by such patients. One of the most frequent dangers to patients who have been sent to regions far from their homes is their impatience to return (especially if they have not done very well) as soon as the first few days of hot or cold weather arrive. In the Southwest, when the weather becomes very warm, usually in April, they insist on returning to the raw air of the North. In the mountains they want to run away with the first evidence of snow or cold. This could often be obviated if the home physician held a stronger control over the patient in his absence. They will not heed the advice of the local physician, whose control over them is not so strong as that of their home adviser. A quick gain, a quick return to their homes, and a quick return of the trouble is the frequent history of this disease.

Journal of the American Medical Association, March 13, 1909.

The Unity of the Medical Sciences.—A. T. Bristow points out that the understanding of the complex human body calls for assistance of all the natural sciences and this brings about a unity of all the branches of knowledge represented in medicine. There is between sciences, however, one common bond of union, namely, that they all have for a foundation the mother of all sciences, logic. No science has suffered more from fallacies than medicine, and he shows how the various popular medical delusions have their basis in false reasoning and faulty observation. Besides the matters that affect principally the individual where these fallacies have done their work, he takes up more particularly the questions of sanitation and shows how much the world has suffered from faulty practice and reasoning in this regard. The address is full of practical illustrations and he concludes with the plea for a national department of health and points out the need of such a department. It should be out of the reach of the politicians and conditions are constantly crowding us to realize the necessity of such a governmental department.

Neuroses and Pelvic Disorders.—Clara T. Dercum says that the symptoms of the two great neuroses, neurasthenia and hysteria, are constantly being misunderstood in their relation to pelvic disease. A close study of these disorders proves that true organic pelvic disease plays but an insignificant part in their development. Their real exciting causes must be looked for in environment plus heredity and in the stress to which adolescent and adult life is subject. The local symptomatic pain and general indications of ill health that may accompany pelvic disease do not of themselves constitute true functional neuroses, such as neurasthenia and hysteria. They manifest themselves symptomatically with the pelvic disorders, as they might with any other visceral disease. The fallacy of the doctrine of "reflex nervous disorders" has been demonstrated beyond dispute with our increasing knowledge of nervous diseases. She reviews the principal symp-

tions of neurasthenia, the indications of motor and mental fatigue, the aches and pains, the gastrointestinal and circulatory disturbances and their consequences, and the multitudinous phenomena of hysteria, especially those that simulate or suggest pelvic disorder, and gives an analysis of 412 cases, in tabulated form. The statistics, she says, do not even show that neurasthenia or hysteria exist in pelvic diseases as in other visceral conditions and certainly do not warrant operations on the pelvic and other viscera without positive surgical indications. She particularly speaks against operating for uncomplicated retroversion. No one will deny that when the uterus is dislocated, that is, fixed by adhesions, surgical measures should be employed to free it after medical ones have failed, but it should not be subjected to a new dislocation by fastening it to the abdominal wall. The pelvic floor should always be repaired when lacerated, as it is so intimately connected with the support of the uterus. But in all inflammatory conditions of the pelvic organs induction of hyperemia, that is a fresh supply of blood to the parts, presents the only means of cure, and this can best be induced by frequently repeated hot douches, glycerine tampons, hygroscopy, electricity, menstruation, and gestation. From a close observation and study of these tables she thinks the gynecologist of the future, when he recognizes the significance of the neurologic simulation of pelvic disease, will endeavor to have the fewest possible operations to his credit instead of the greatest number. The conservation of normal pelvic organs and the restoration to health by medical means of those that are diseased will be his highest aim.

Cancer of the Uterus.—W. B. Moulton quotes Crile, that one woman in every eight who reaches the age of thirty-eight dies of cancer (including all forms), and refers to the statistics of Werthheim in uterine cancer as compared with those of other operators, who cure only from 5 to 8 per cent., while he reports 22.5 per cent. of all patients cured. The explanation lies in the fact that he sees the patients earlier, those that come before surgeons in this country are past successful treatment, at least in the majority. A cancer of the cervix that has progressed so far as to be diagnosed unhesitatingly by the touch, eye, or history can be pronounced to have reached the border line between possibility and impossibility of cure. Our hope here lies in the general practitioner, who must start a campaign of education among his female patients and himself consider as serious and not neglect all disturbances of menstruation occurring in the cancer age. Complete surgical extirpation is at present our only method for the cure of cancer of the uterus, but the percentage of cures is much below what it should be. Every woman who has borne children should be examined, Moulton believes, by a competent physician at least once every year until she is fifty-five years old, and the effect of the adoption of educational measures and examination would be the prompt discovery of an enormous number of cancer cases in their very incipiency.

Ancient Quackery.—J. J. Walsh points out that quackery of the most modern type, with all the traits we know so well to-day, abounded in ancient times and is characteristically illustrated in the folk lore of the earliest antiquity. The Arabian Nights are comparatively modern, but they are, as we know them, tales derived from still earlier legends going back to the times of Herodotus and before, even to the central plateau of Asia, where the human race originated. He illustrates his point by one of these tales which has come down to us showing the readiness of the quack to promise to cure anything and everything, and which is as modern in its exhibition of human nature as any of the impositions used to prey on the public in the present day. Man does not essentially change during the ages and is the same in the environment of the Orient as in the centers of civilization.

Bloodless Hysterotomy.—A. E. Hertzler describes his methods of avoiding excessive hemorrhage in the removal of uterine fibroids, by a scheme of preliminary ligation of the blood-vessels. The steps are as follows: "(1) The peritoneum is incised along one side of the tumor. (2) The tumor is raised out of its bed by blunt dissection sufficiently to reach the point of blood supply. (3) This having been found, a ligature is passed and tied and the tumor severed. (4) The peritoneum is incised the remainder of the way around the base and the tumor removed. The peritoneal edges are then approximated by a running plain catgut suture." Each vessel must be separately secured in this preliminary ligation. In some cases, however, in which the tumor is deeply situated or has a wide base, or in case of multiple tumors close together calling for removal of part of the uterus, the area of blood supply is diffuse and such preliminary ligation is impracticable. For these cases he has devised what he calls "bloodless hysterotomy," in which he attempts to apply the principle of the Esmarch bandage to the uterus. The procedure consists in placing a rubber-covered clamp on either side of the organ in such a manner as to compress the uterine vessels sufficiently to control the circulation without injuring their walls. They are so applied that their tips lie in the triangle formed by the ureter externally, the cervix internally, and the uterine artery above. The base of the forceps passes externally to the ovaries and tubes, thus preventing any undue compression of the tube. The clamps once applied, the tumor can be removed, and, if necessary, the uterus can be opened with immunity. After removal of the tumor the resulting defect is closed by sutures, two layers usually being required. If necessary, some additional sutures are placed and any large vessels exposed are separately ligated, as in the amputation of a limb. The clamps illustrated in the cuts accompanying the article are Moynihan stomach clamps ground down sufficiently to give them elasticity enough to prevent undue injury to the vessel walls. The curved handles are convenient when the abdominal wall is thin; with thick abdominal walls the straight Moynihan anastomosis clamp can be used with advantage.

Pulmonary Hemorrhage.—J. B. Fish divides pulmonary hemorrhages into three types according to the pathological conditions: (1) Capillary hemorrhage, resulting from hyperemia of the bronchial mucosa or lung tissue, associated with a relaxed or eroded area of mucous membrane; (2) hemorrhage resulting from the destruction of lung tissue associated with rupture of small or medium-sized blood-vessels (arterial or venous hemorrhage); (3) hemorrhage resulting from the rupture of a large vessel. By far the vast majority of cases belong to the first type and may be produced by many causes, such as chilling of other agencies increasing blood pressure. The precursory signs of the bleeding are to be noticed and the character of the blood discharged; whether it was preceded by tightness or feeling of oppression in the chest, and whether it is moderate or sudden and copious. By these we can judge whether the hemorrhage is of the congestive type. Fish gives directions as to the management of a case, consisting of the usual prescription of quiet, attention to the bowels and kidneys, and, in congestive cases, the use of nitrite of amyl or potassium nitrite, and, after the bleeding is under control, nitroglycerine, say 1/50 grain every three or four hours. By regulating this drug, according to a blood-pressure apparatus if possible, the recurrence may frequently be avoided. A small dose of morphine at bedtime may be given for a troublesome cough. To avoid after-effects, he is in the habit of giving ammonium muriate combined with codein, both in small doses. He also, as an eliminant, gives magnesium sulphate, one dram three times daily. Above all, care should be taken not to overmedicate. In the second type of cases, due to the rupture of a small vessel, the first aim should be to reduce the force of the heart and lessen the flow through the lungs, and here he thinks aconite the best agent. In addition, he uses the calcium salts to increase the coagulability of the blood. Occasionally the subcutaneous or rectal injection is of great service, and ligation of the limbs may be of value. Ergot, he thinks, is of no value and may do harm. In the third type, when a large vessel is ruptured, little can be done but in tiding over the period of collapse and afterward combating the anemia, even to the extent of transfusion of salt solution. So-called vicarious hemorrhage, if moderate in character, requires no special treatment, except keeping the patient quiet and perhaps putting him to bed. Hysterical hemorrhage should not be taken too seriously nor yet neglected, and if evidence of malingering is lacking such patients should be treated for the blood spitting without regard to the nervous complication. In conclusion, Fish mentions malingering, which can usually be detected by one on the lookout. In most cases a pulmonary hemorrhage means tuberculosis, but we must not forget that cases of blood spitting in bronchiectasis and mitral stenosis are by no means rare.

The Lancet, March 6, 1909.

Postural Cardiac Murmurs. E. L. Moss notes that a systolic murmur heard over the upper part of the sternum

unaltered by respiration, may sometimes be produced by raising the arms to a shoulder level, as in the position of holding up the shirt to expose the chest for examination. He relates brief notes of three such cases. His attention was first called to the matter when endeavoring to decide whether the so-called "retraction" murmur occasionally found in tuberculous children was really due to pressure of involved mediastinal glands or some of the large venous trunks or whether it was a sign occasionally found in healthy cases. In investigating adults (as the three cases reported were) he found the murmur described. At first he thought it might be produced by traction on the trachea and bronchi, causing kinking of or pressure on the aorta or pulmonary artery, but since the murmur is produced by raising the arms without backward extension of the head, it seems more likely that the position causes an expansion of the lower part of the thorax, increasing the negative pressure within which allows a temporary dilatation of the aortic arch. Whether or not the normal aorta would be affected in this way it is not easy to say.

The Advisability of Removing the Appendix at the Time of Opening the Appendicular Abscess.—H. S. Clogg operated on 131 cases of localized appendicular suppuration. In 23 the appendix was removed at the same time, and in 108 left. Of complications in the second division cases there were: portal pyemia, 1; subphrenic abscess, 3; pelvic peritonitis, 1; prolonged duration of the sinus, 18; recurrence of suppuration, 9; recurrent non-suppurative appendicitis, 11. The advantages of removing the appendix at the primary operation are thus enumerated: (1) The wound heals quicker. (2) There is less tendency to imperfect drainage, as the supply of infection is removed and the abscess cavity is so thoroughly opened that it may be drained from the most favorable position. (3) The rare complication of a portal pyemia following a persistent sinus may be abolished. (4) An inflammation spreading up the right colon to the subhepatic or subphrenic regions may be anticipated and cut short by a timely lumbar drain. (5) The exploration of the abscess cavity will enable any concretions which have escaped from the appendix to be removed. (6) The persistent sinus and frequently recurring breaking down of the scar will be practically abolished. (7) The risk of ventral hernia is by no means increased but may be actually lessened. (8) The permanent changes in the wall leading to stenosis of the appendix and the very frequent presence of concretions in the lumen which have not escaped into the abscess cavity are most potent predisposing causes to recurrent appendical trouble.

An Investigation into the Clinical Significance of Albumosuria and Its Value in Diagnosis and Prognosis.—J. Henderson has made special investigations with special reference to pneumonia and nephritis. Out of 78 pneumonia cases (of which 15 were fatal) 28 cases showed albumin, and of these 12 were fatal. These 28 patients all showed a severe type of symptoms during the primary fever and usually they were delirious. The presence of albumosuria must be regarded therefore as an unfavorable sign. Over 80 cases of nephritis were examined. Albumose is rarely present in acute and subacute nephritis. When present it may be associated with uremia and herald its onset. Albumosuria appears to indicate the existence of a chronic condition and is most constantly present in the chronic parenchymatous variety. In such cases the albumosuria is often associated with, though it does not necessarily indicate, an early fatal issue. In 50 cases also of heart disease albumose was found in 5 and 2 of these were ulcerative endocarditis both of which proved fatal. It should always be looked for in pneumonia and in cases in which suppuration is suspected. The author discusses the relative value of the various tests for this urinary ingredient. He commends the use of a 20 per cent. solution of caustic alkali in distilled water to which enough copper sulphate is added to give it a faint blue tint. The urine is floated on the surface of this solution and a rose-pink color at the area of junction indicates the presence of albumose.

British Medical Journal, March 6, 1909.

Observations on Pleural Pains and Adhesions.—J. T. Maclachlan says that after four years' careful observation he has come to the conclusion that so-called pleurodynia is in reality a localized pleurisy and that they are mostly of a tuberculous origin. In his experience the pains are referred to certain well-defined regions, namely, where the lungs divide into their lobes or the free margins of the lungs, around the right nipple, left border of the heart, left lower axillary region, and points a little below the apex of each scapula. These areas may be made out by gentle percussion, or "tactile" percussion in which the sense of resistance is strongly appealed to. Ordinary percussion goes through these areas of pleurisy and brings out the ordinary lung sound. Auscultation is not as valuable as is percussion in making out such superficial areas of dullness on the surface of the lung. If the dullness is considerable, the inspiratory murmur may be fairly distinct and the expiratory murmur faint and unusually short as compared with that over the sound pleura and lung. Inspection may show deficient expansion and contraction. All these signs of pleural adhesion are a danger signal to the patient to ward off lung tubercle. If a patient complains of a cough, expectorates, and has a sharp pain in the chest, he has, in all probability (if we can rule out lung cancer), lung tuberculosis. If the sputum contains cheesy-looking particles, it signifies the presence of softening. Hence the three evidences indicated will in all probability correspond to bronchitis, pleurisy and tuberculous pneumonia, or, in other words, phthisis pulmonum.

Treatment of Cancer by the Use of Potassium Bichromate.—J. Fenwick summarizes the facts in nineteen personal cases and adds three more from the experience of a colleague. He injects from seven to ten minims of a sublimate solution of the bichromate of potassium into the substance of the tumor. He claims excellent results in rodent ulcer and epithelioma. Details of the individual cases must be read by those interested.

The Natural Cure of Cancer.—W. S. Handley lays down the following unrecognized law of cancerous growth: Every aggregation of carcinoma cells has a definite life-cycle, and, after increasing in size for a varying period and at a varying rate, tends spontaneously to undergo degenerative and fibrotic changes. These changes extend from the center of the mass centrifugally to the periphery, lead to its shrinkage, and terminate in the replacement of the aggregation of cancer cells by a fibrous scar. The author says that the literature of cancer therapeutics does not contain the record of a single fact which cannot be paralleled among the histories of untreated cases. One of the most striking facts brought out by his investigations is that the permeative spread of cancer is followed by an almost coextensive destruction of the lymph vascular system and by contraction of the network of fibrous threads which replace the lymphatic vessels. In the mamma the perolymphatic fibrosis accounts for the nipple retraction, flattening and shrinkage of the breast, and adhesion to the skin and fascia, and all these are to be regarded as attempts at natural cure. Their absence in a given case is of no value as against malignancy. The leathery thickening of the chest skin is primarily a pachydermia or lymphatic edema of the skin, due to a destruction of the fascial lymphatic plexus and to consequent lymph stasis. Only in the later stages is the skin actually invaded by cancer cells. The permeation theory of dissemination explains also the brawny arm of breast cancer, which is not due merely to pressure of a mass on the axillary veins. It is a pachydermia affecting the arm in consequence of a lymphatic fibrosis, and is to be regarded as an evidence of activity of natural curative processes than as a direct symptom of cancerous growth. The author believes that the general principles of the open-air treatment as laid down for tuberculosis are applicable here. In each instance the object is to promote a fibrosis. The treatment as applied to cancer would need, doubtless, some modification, as less food and more exercise. Yet under no circumstances whatever, the author says, should the treatment be recommended as a substitute for operation if operation is possible.

Berliner klinische Wochenschrift, February 22, 1909.

Pancreatitis and the Cammidge Reaction.—Eichler and Shirokauer have studied this reaction experimentally by producing disease of the pancreas in dogs by tying the pancreatic vessels, or ligating the organ itself. The reaction was not present in any case before the operation. Only a few gave a positive reaction after the operation, and the reaction was never constant, but appeared and disappeared without any discoverable change in the condition of the animals. Two patients with disease of the pancreas did not give the Cammidge reaction, although the existence of a lesion was diagnosed by operation. In another article Caw and Wörner report two cases of pancreatic disease in which the reaction of Cammidge was obtained. These authors think that glycosuric acid has something to do with the appearance of the crystals described by Cammidge. They have also observed that the width in content of the feces is very much increased in the presence of pancreatic disease.

Book Reviews.

A Text-Book of General Pathology. For the use of Students and Practitioners. By J. Martin Beattie, M.A. (N. Z.), M.D. (Edin.) Professor of Pathology and Bacteriology, University of Sheffield; Hon. Pathologist, Sheffield Royal Infirmary and Royal Hospital, and W. E. Carnegie Dickson, M.D., B.Sc., F.R.C.P. (Edin.), Lecturer on Pathological Bacteriology and Senior Assistant to the Professor of Pathology in the University of Edinburgh; Assistant Pathologist, Royal Infirmary, Edinburgh With 162 illustrations and four colored plates from original preparations. Philadelphia: P. Blakiston's Son & Co., 1908.

It has become somewhat the fashion to speak, or at least to think, rather disparagingly of the purely morphological aspects of the study of pathology and to consider that during the coming years the more important work will be done in the inestigation of problems of biochemistry. While this view is no doubt sound enough in the main, there is no reason to suppose that much progress is not still possible in the domain of the "old" pathology or to abandon even temporarily the microscope and staining fluids for the test tube and distilling flask. No reader of the present volume can fail to be impressed with the immense advances that have recently been made in numerous departments of the subject or to be stimulated to renewed interest in matters that he has perhaps already come to regard as closed chapters.

The book is intended primarily as an exposition of the teaching of the Edinburgh school, the first in the United Kingdom to establish a chair of Pathology and always preeminent in this field, and presents views on many important topics, such, for example, as the manner of formation of the different types of infarcts, and the relation between arterial changes and the lesions of the kidney, that if not altogether novel are at least deserving of widespread attention. The entire section on the various degenerations is especially noteworthy and is illustrated with photographs and colored plates of great interest. Thrombosis also is discussed at greater length than is usually done, while in the chapter on inflammation and repair the recent work on the origin and nature of the various cell forms encountered is presented with much clearness and critical judgment. The authors have also been particularly successful in the sections on tumors, founding their classification on Adami's system in which the tissues are divided into the lepidic or lining membrane tissues, and the hylic or primitive pulp tissues, with a resulting grouping of tumors into two great orders, first the teratomata, and secondly the blastomata, or body tissue tumors, which are either lepidomata or hylomata, the former including the carcinomas and the latter the sarcomas.

The animal parasites are described and figured in greater detail than usual, and the closing chapter on immunity forms a most satisfactory summary of the present hypotheses in this regard. While well adapted to the needs of the student, the book is comprehensive enough to serve as a work of reference and its agreeable style and typographical attractiveness should commend it to the casual reader.

Scientific Laboratory Help in Diagnosis. A Little Book for the Guidance of the General Practitioner and the Specialist, Showing the Usefulness and Advantage of the Laboratory Report. Chicago: The Abbott Alkaloidal Company, 1908.

This pamphlet contains a few tables showing the laboratory findings in uranalysis, examination of gastric contents, and blood examinations. It will doubtless be of use to laboratory workers and others.

A Manual of Bacteriology. By Herbert U. Williams, M.D., Professor of Pathology and Bacteriology, Medical Department, University of Buffalo. Revised by B. Meade Bolton, M.D., Washington, D. C., one time Associate in Bacteriology, Johns Hopkins University; Chief of the Bureau of Health Laboratory, Philadelphia, Pa.; Professor of Pathology and Bacteriology, University of Missouri; Bacteriologist, Bureau of Animal Industry, etc. With 113 illustrations. Fifth Edition, Revised and Enlarged. Philadelphia: P. Blakiston's Son & Co., 1909.

This book is designed primarily for medical students, and as it is now in its fifth edition it may be assumed to have fulfilled its purpose. The present edition has been revised and brought up to date, so that it is well abreast of modern bacteriological knowledge. As was stated in an earlier edition, "The purpose of this book is to give in the smallest possible space the facts which a physician must know, with some of those which it is desirable that he should know, and a little of that which he may learn if his needs or inclinations lead him to go further." For students and practitioners this is just the book to begin with, and in connection with good laboratory instruction it should make the study of bacteriology both sound and attractive. The references to the literature of the subject are judiciously selected, and are sufficient to invite further investigation without bewildering the student.

Meat and Food Inspection. By William Robertson, M.D., D.P.H., F.P.S., Medical Officer of Health, Leith; formerly Medical Officer of Health, Perth and Paisley; author of "Practical First Aid" (third edition); joint author of "Sanitary Law and Practice"; Lecturer on Public Health, Royal College of Surgeons, Edinburgh; Lecturer of Public Health, Women's College, Edinburgh; Examiner in Public Health Conjoint Board, Scotland; Examiner in Public Health, Incorporated Sanitary Association, Scotland, with Regulations Governing Meat Inspection in the United States, by Maximilian Herzog, M.D., Professor of General and Comparative Pathology in the Chicago Veterinary College; Pathologist of the Michael Reese Hospital; Expert of the Chicago Stock Yards Investigation Commission of the Illinois Manufacturers and the Chicago Commercial Associations; Late Pathologist to the Bureau of Science, Manila, Philippine Islands. Chicago: W. T. Keener & Company, 1908.

At the present time the pure food question is one that interests nearly everybody; and since the Government has taken the matter in hand the importance of the subject is greater than before. This work on food and meat inspection is a valuable addition to a somewhat scant list of books dealing with this topic. The subjects discussed in the volume are: Site, structure, and various types of cowsheds, piggeries and stables: milk-supplies; tuberculin and mallein tests; preparation of vaccine lymph; slaughterhouses; the appearance of healthy and diseased animals; anatomical considerations; methods of slaughter; the appearance of the meat of animals under varying conditions; preservation and storage of meat; the diseases most commonly seen in the abattoir; other conditions met at the slaughter-house; fish, oysters, mussels; ptomain and food-poisoning; retail shops and farm produce; prosecutions, various examples. Then follows a section of nearly two hundred pages on the law relating to food inspection, housing of animals, etc. Although the whole subject is discussed from the standpoint of English law, the information contained in the volume is most valuable, and will be found equally applicable to the conditions as found here except, of course, in the details of the legal enactments; and many of these latter may serve as a guide for future use. The book is valuable to all interested in the subject, whether health officers, sanitarians, practitioners, or laymen.

Obstetrics for Nurses. By Joseph B. De Lee, A.M., M.D., Professor of Obstetrics, Northwestern University Medical School; Obstetrician to Mercy, Wesley, Provident, Cook County, and Chicago Lying-in Hospitals; Lecturer in the Nurses' Training Schools of Same. Third edition, thoroughly revised and enlarged. Philadelphia and London: W. B. Saunders Company, 1908.

This volume really contains two subjects, namely, obstetrics for nurses, and obstetrical nursing; and these are so admirably combined that not only are their mutual relations well presented, but the book is so complete that nurses will not require any other text-book on either subject. There is but little new matter in this third edition; the chief additions being found in the section on infant feeding, and in the glossary. The work is well and liberally illustrated, and can be recommended to nurses as a very useful book.

Aids to Tropical Medicine. By Gilbert F. Brooke, M.A. Cantab., L.R.C.P. (Edin.), D.P.H., F.R.G.S., Port Health Officer, Singapore; Lecturer in Hygiene and Examiner in Chemistry and Physics to the Medical Council of the Straits Settlements; Formerly Government Medical Officer and District Commissioner, Turks and Caicos Islands, West Indies. New York: William Wood & Co., 1908.

The present volume is intended as a students' notebook on the subject of Tropical Diseases, the study of which has received some impetus in the last few years. The subject matter is arranged alphabetically; and a concise and accurate summary of each of the more important tropical diseases is to be found there. The author writes from an extended personal experience, and gives valuable bibliographical references. The book is small, but useful; and it is the first compend that we have seen on this subject

Society Reports.

NEW YORK ACADEMY OF MEDICINE

SECTION ON SURGERY.

Stated Meeting, Held February 5, 1909.

DR. ELLSWORTH ELIOT IN THE CHAIR.

A Further Report on a Case of Fracture of the Os Magnum.—Dr. EDWARD W. PETERSON made a further report on this case which he had presented at the January meeting of the Section. Dr. Connell at that meeting did not believe a correct diagnosis had been made. Dr. Peterson said that they both were right, and both were wrong. The radiograph did not show a fracture of the os magnum, but the patient did have such a fracture.

A Case of Fracture of the Os Magnum.—Dr. KARL CONNELL presented a man, forty-three years old, who fell upon his left hand seven weeks ago. He was rendered unconscious at the time. He came to the hospital later with an injured wrist. It was learned that he had sustained a Colles' fracture, a fracture of the os magnum, and a forward dislocation of the semilunar bone. Four weeks after the injury he had 60 per cent. supination, full pronation, and 20 degrees of extension of the joint. The scaphoid bone was also broken. Radiographs were shown.

A Further Report on a Case of Foreign Body in the Intestine.—Dr. W. S. SCHLEY made a further report on this case, which he had presented at the previous meeting of the Section. A stick seven and one-eighth inches long was presented. A diagnosis was made of foreign body in the intestine when the patient entered the hospital, and this was correct; a distinct pointed mass was felt one and a half inches above the umbilicus and it could be moved about freely. The patient claimed that he had swallowed it. On the following day he complained of a sense of irritation in the rectum, and the house surgeon then took a pair of sponge forceps and extracted the piece of wood. The question arose as to how the patient could have swallowed such a mass; the probability was that it had been introduced through the anus. He certainly must have had an exceedingly lax sigmoid.

Imperfectly Descended Testicle; Operation and Transplantation to the Scrotum.—Dr. W. S. SCHLEY presented this case. The boy entered the hospital with an undescended testicle; it could not be pushed down into the scrotum, and it seemed wise to try some operative procedure to bring it down. An absolute denudation of the cord was done, stripping it absolutely free of every bit of tissue. The Basinni method was used, and with good results.

Dr. ALEXIS V. MOSCHCOWITZ said the results obtained by Dr. Schley were undoubtedly the best he had ever seen in such a case. He had tried all the methods advised for undescended testicle and he had come to the conclusion that a method as good as any was that of Deaver. In the case presented there seemed to be perfect mobility of the testicle.

Extensive Extravasation of Urine with Sloughing of Skin and Cellular Tissue of the Penis; Skin Grafting.—Dr. SCHLEY reported the case of a man who had an extensive extravasation of urine and who was in a neglected condition when he entered the hospital. The whole skin covering the penis was gangrenous, and there were pockets of pus in the scrotum and in the groin. The skin covering the penis was cut away and skin grafting done with good results.

Nephrectomy for Hydronephrosis.—Dr. A. S. VOSBURGH presented a woman who had walked into the sharp point of a table and received a severe injury to her side, and was ill for some time as the result. Physicians pronounced her suffering due to a loose kidney. For a number of years she had repeated attacks of pain in this side, and the pain was usually associated with vomiting. For two years before the first attack she was absolutely free of symptoms, except a feeling of weight and a sense of discomfort in that side. Her illness preceding her entrance to the hospital was of several days' duration. There was pain in the lower right part of the abdomen, vomiting, temperature, etc., and a tentative diagnosis of appendicitis was made because of the localization of the pain and the temperature of 101°. Upon a careful examination a mass the size of a grape fruit was found in the right lower quadrant of the abdomen. It was not particularly painful except on deep pressure. The urinary examination was negative. The blood count showed 13,000 leucocytes, and the differential count showed 86 per cent. polymorphonuclears. The tumor occupied the site of the right kidney, and was retroperitoneal. The appendix was found to be normal; it could not be pulled into the wound, and so the abdomen was closed and the patient turned upon her side and an ordinary nephrectomy incision was made, discovering a large hydronephrosis or hemonephrosis. The fluid was aspirated, and an enucleation done. Having removed the tumor, there was found a second mass which looked like an infiltration from a hemorrhage. Although it was quite extensive, it was thought best to let it alone. The patient made an uninterrupted recovery, except that she had temperature for some time. The amount of urine passed during the first twenty-four hours was 39 ounces; during the second day, 46 ounces; during the fourth day, 49 ounces; during the fifth day, 25 ounces; during the sixth day, 76 ounces; during the seventh day, 39 ounces; on the tenth day, 49 ounces. Much interest was attached to this case because of the cause of the hydronephrosis; the contents of the hydronephrotic sac were hemorrhagic.

Dr. W. A. LUCKETT reported a case of hydronephrosis of intermittent character. The patient had been suffering from pain in the right side, and passed daily several quarts of urine. The diagnosis was an intermittent hydronephrosis. At operation the pelvis of the kidney was opened, and there was found a small calculus which acted as a ball valve at the mouth of the ureter. This evidently was the beginning and cause of the hydronephrosis.

A Case of Traumatic Aneurysm.—Dr. A. S. VOSBURGH presented a man who had received two pistol shots in the right arm, one bullet penetrating the forearm. At the first examination no pulse could be detected at the wrist, and he thought an injury to the brachial artery had occurred. The upper arm soon began to swell, and he noted expansile pulsation. At operation he found that the bullet had plowed along the brachial artery, and there had been formed a false aneurysmal sac. The median nerve had been wounded as well; the bullet had broken the axis cylinder. Of course, the muscles supplied by this nerve were involved, being paralyzed. There was a flattening of the thenar eminence. Restoration of function had been prompt.

Acute Cholecystitis During the Third Week of Typhoid Fever.—Dr. JOHN DOUGLAS presented a man, forty-eight years old, a Swede, who had been admitted to Bellevue Hospital with typhoid fever on August 15, the disease having started on August 7. He went to bed on August 8. He had hemorrhages from the bowel. He began to feel better, but soon he felt pain in the right hypochondrium. Fever accompanied the pain. His temperature was 103.2°, pulse 20, and respirations 22. The number of leucocytes was rather high for a case of typhoid alone. He ran a normal course of the disease up to August 24, when he had a temperature of 105.2°, and he complained of pain in the right hypochondrium. He had a chill on August 31, and a second one on September 3, with a temperature of 105.3°. The temperature suddenly

dropped to 97.3°, pulse 80, and respirations 20. The leucocytes numbered from 13,000 to 17,000, and the polynuclears were 92 per cent. The pain in the right hypochondrium was marked. He had a distinct cholecystitis. Under cocaine anesthesia an incision was made in the right hypochondrium; no pain was felt, and the patient stood the operation nicely. When the parietal peritoneum was touched, however, severe pain was felt. On the day following the operation the temperature was 98°, pulse 104, and the patient was in good condition. At the operation about fifteen small, light-colored gallstones were removed. Six days after the operation the temperature again rose, and there appeared to be a lapse of the typhoid. Pure culture of the bacilli was taken from the gallbladder. The wound continued to discharge bile for two months after the operation, and during all that time pure cultures were obtained from the bile. However, no cultures could be gotten from the stools. On the eighty-seventh day of the disease, fifty-seven days after the operation, he had a relapse of his typhoid, which ran an ordinary course. The wound continued to discharge. In December he did a cholecystectomy. The operation was comparatively easy because there were so few adhesions. The interest in this case was the attack of acute cholecystitis occurring during typhoid fever, and the operation under local anesthesia.

Large Phagedenic Ulcer of the Abdomen.—Dr. W. A. Luckett reported this case. He especially emphasized the good results following the free use of the cautery in this case.

The Surgical Importance of the Visceral Crises in the Erythema Group of Skin Diseases.—Dr. Henry M. Silver read this paper. Osler had written five articles on this subject, and reported twenty-nine cases. He reported five groups of crises as follows: (1) The colic crisis which occurred in pure angioneutotic edema. (2) Cases in which the skin lesion was an urticaria. (3) Cases of arthritis associated with erythema and colic. (4) Cases in which the lesions were those of erythema multiforme, with or without edema. (5) A remarkable group of cases, very difficult to recognize, with only recurring colic and nothing else. The attacks of colic might recur for years and years before the skin lesion appeared. Of the above five crises, the first and third were the ones that Dr. Silver said he would consider. In the first group, Osler had reported two cases, and Harrington, of Boston, one case. Morris had reported a case in which the attacks followed the use of a stomach tube. Angioneurotic edema was more common among males, and occurred at all ages. The tendency to recurrences remained throughout life. It was fatal when it attacked the larynx. In families that had escaped the disease, it was less likely to be transmitted than in those families where the disease had occurred. Out of eighty cases reported by one writer, thirty-three occurred in families that had had, or did have, the disease. In the third group, those cases of arthritis associated with purpura and colic, was the so-called Henoch's purpura, a case of which Dr. Silver reported in detail. Among the symptoms referable to the alimentary tract was the abdominal pain, colicky in character; with it the patient cried and tossed about. The pain was followed by nausea and vomiting of blood-stained matter. The breath was very offensive and had the odor of acetone. Constipation might be a marked feature. The act of vomiting and the movements of the bowels seemed to give relief from pain. The physical examination revealed nothing abnormal. These attacks had a great tendency to recur. The abdominal symptoms were probably due to a serous or hemorrhagic effusion into the coats of the intestines. The clinical history and the post mortem showed that these hemorrhages occurred into the intestinal wall. Hemorrhages from the nose and throat might occur, and loosening of the teeth as in scurvy. The knees, ankles, elbows were the joints most frequently involved. There was a slight leucocytosis, usually below 14,000, and usually a normal differential count. The one symptom which was almost impossible to describe was the facial appearance of the patient, which pointed to serious illness. The eruption might be a diffuse erythema or an intense hemorrhagic purpura, with shades of intensity between. The essential cause was not sought for in the microorganisms producing leucocytosis. The symptoms of purpura might be an undiscovered toxic process; a toxic action on the endothelial cells leading to a discharge of blood had been assumed to be a cause. The most important surgical disease to be differentiated from Henoch's purpura was intussusception. The pain was sudden and was preceded by diarrhea in both diseases. A slight rise of temperature was not uncommon in both. Vomiting was an early symptom in both diseases. The occurrence of tenesmus was in favor of intussusception. The presence of tumor was the crucial test and especially was to be relied upon to make a positive diagnosis of intussusception. No tumor was palpable in 60 per cent. of a series of twenty-six cases of intussusception. However, hemorrhage in the abdominal wall may give a tumor, but this might be reduced by manipulation. Abdominal tenderness was not present in Henoch's purpura, and there was a slight leucocytosis and a normal blood count. Appendicitis might be differentiated from Henoch's purpura by the sudden onset of the pain, and by palpating a tumor later in the disease when abscess formation had occurred. It had not the doughy feeling that the tumor of an intussusception had. In appendicitis abdominal tenderness and rigidity were marked, the bowels were constipated, and there was little or no tenesmus or bloody stools containing mucus. Appendicitis was not limited to any age, there was no leucocytosis, there was no eruption or joint pains, there was no hematuria, there was no previous history of the attacks of paroxysmal pain. After a careful study, the following practical results were offered: (1) In children and young adults suffering from colic, the greatest care should be taken to obtain a complete history, personal and family, which might bring out any facts of previous attacks either of skin lesions, arthritis, or intestinal crises. (2) One should make the most careful inspection of the skin for angioneurotic edema, purpura, or erythema. (3) An accurate examination of the blood, with the differential count, gave a very important aid in differentiating those cases which needed surgical treatment.

Dr. Walter Lester Carr opened the discussion from the pediatric standpoint. He had recently seen a boy of seventeen years who had been referred to him, and who gave a rheumatic history. He had a mitral murmur. He was lying in bed with the peculiar facial expression mentioned by Dr. Silver. There was some abdominal distension. The boy had pain in and swelling of the knee joint. There was also a distinct nodule below the left knee and the tissues about appeared as if bruised. A very careful examination of the abdomen revealed enlarged lymph nodes; there were also enlarged lymph nodes in both groins. There was some rigidity of the rectus muscles. The bowels were constipated, the tongue was coated, and an analysis of the urine showed the presence of acetone, a faint trace of albumen, and some blood casts. The leucocyte count was 12,000 and the differential count was normal. The boy's recovery was slow. This case probably belonged to the third group of cases described by Dr. Silver. There was a swelling, or prominence of the abdomen which was rather unusual in these cases; most of the cases had a retracted or flat abdomen. These cases Dr. Carr thought were unique

Dr. L. E. La Fetra believed that these cases must be exceedingly rare, even rare to those who saw many cases of purpura and other hemorrhagic types of disease in chil-

dren. He had never seen a case. The nearest approach to this disease was the attacks of asthma which accompanied the erythematous group of disease.

Dr. William L. Stowell said he could recall but one case of visceral crisis which came under his own observation. The patient was a girl, twenty years old, but she was not larger than a child of thirteen or fourteen should be. She had pain in the abdomen with vomiting, and the urine contained blood. The pain in the abdomen and the vomiting continued, and blood passed from the bowels. Soon the blood in the urine disappeared, and nose bleed and bleeding from the gums appeared. The leucocytes numbered 14,000 and there were 2,000,000 red cells. Dr. J. Lewis Smith, as early as 1865, had collected 40 cases of purpura with marked gastrointestinal disturbances, but he did not describe them in such a way as to place them in this class of cases, although they were very closely allied.

Dr. John F. Erdmann said that he had reported 41 cases of intussusception and in 50 per cent. a tumor was palpable. It was very difficult to make a diagnosis of those cases which were allied to Henoch's disease, and he reported an interesting case in which the diagnosis of intussusception was made. He operated upon the child, but the child died. An autopsy was not permitted. The gums were swollen and bleeding. The case was one of scrobutus.

Dr. Charles A. Elsberg continued the discussion from the surgical standpoint. He said that during the past two or three years three cases coming under this group were seen at the Mt. Sinai Hospital. In two an operation was performed, while in the third the condition was recognized and no operation was performed. The question arose in the first case whether or not the picture presented by the patient was not the one described by Osler; but the patient looked so ill that he decided to operate. He removed the appendix; it was a case of appendicitis. Two or three days later he learned that he was mistaken in his diagnosis, because the patient developed pain in the various joints and a rash appeared over the elbows and knees. The second patient gave a history of attacks which were supposed to be due to appendicitis and a normal appendix was removed. Two or three days after the operation, abdominal colic with an erythematous eruption appeared. He did not operate upon the third case, because the typical symptoms of appendicitis were absent. The child, however, was kept under observation in the hospital and soon there appeared pains in the joints, and an erythematous eruption over the extensor surfaces of the elbows, ankles and knees. Another case supposed to belong to this group turned out to be one of early measles with abdominal symptoms.

Dr. Alexis V. Moschcowitz reported the case of a child who was admitted to the hospital with a typical attack of appendicitis. He operated and found some clear serum in the peritoneal cavity and an apparently healthy appendix. The glands at the ileocecal junction were bunched. This child later developed a typical angioneurotic edema.

Dr. Edward W. Peterson said that he had recently been called to see a case supposed to be cholecystisis with a view of operating. It turned out to be a case of herpes zoster with abdominal symptoms, and it was in his opinion quite a unique case.

Dr. John A. Fordyce said that the erythema group which, by the occurrence of transitional forms, comprised such affections as erythema exudativum multiform, erythema nodosum, urticaria, the purpuras, scalatiniform and morbilliform erythema, constituted a connecting link between dermatology and internal medicine and illustrated the important interdependence of one set of organs upon another. It had long been known that toxic products of most diverse origin were capable of producing various types of erythemas. This was illustrated by the urticarial, purpuric and erythematous lesions after the administration of drugs or therapeutic sera, as a manifestation of ptomaine poisoning from spoiled meats or fish, after the ingestion of certain aliments by individuals with peculiar idiosyncrasies, or as a result of numerous intoxications of chemical, bacterial or protozoal origin. An attempt to make an independent entity of exudative erythema had signally failed; it was now regarded as only a part of the symptom-complex of a general toxemia. Osler had pointed out that this disease might manifest itself by the visceral complications only, or in addition to the cutaneous eruption and joint lesions there might be involvement of the visible mucous membranes, those of the gastrointestinal and respiratory tracts, the serous membranes, viscera, brain, etc. Since in the vast majority of instances these erythemas were symptomatic of some internal condition, their importance as indicators of such could not be exaggerated. In considering the surgical importance of this group of diseases in relation to internal disorders, numerous instances had come under his observation in which exudative erythemas had developed in connection with acute abscess formation in the skin and elsewhere, ulcerating gummatous lesions in the throat, Pott's disease, gonorrheal urethritis, cystitis, endometritis, salpingitis, etc. They were particularly apt to occur if pus was confined in a narrow canal or under pressure or where spontaneous evacuation was impossible. Suppurative processes of the sexual organs, especially the vagina, were quite prone to give rise to eruptions of erythema multiforme, which, however, disappeared spontaneously when the original trouble was removed. Of the visceral complications, those known as the gastrointestinal crises were the more frequent, especially as a concomitant of the condition known as Henoch's purpura. They consisted of colic varying in severity, vomiting and diarrhea, sometimes with hemorrhages from the stomach and bowels. That lesions similar to the cutaneous ones occurred on the gastrointestinal mucosa was substantiated by clinical observation and the findings at autopsy. Endocarditis and pericarditis had been observed in connection with erythema nodosum, and occasionally pleuritis and pneumonia. Asthmatic and dyspneic attacks might result from urticarial lesions in the respiratory tract and when localized on the glottis might call for tracheotomy. In the several forms of purpura hemorrhages might take place from the nose, stomach, bowels or lungs, into the serous cavities or viscera, and into the brain resulting in apoplectic seizures. That the toxins associated with the erythema group of diseases were not infrequent cause of acute nephritis was shown in Osler's series of twenty-nine cases with seven deaths, five of which died of uremia.

Dr. Frederic E. Sondern said that he had only made one examination of the blood in a case of Henoch's purpura but he had made a large number of examinations of the blood in a similar disorder, *i.e.*, angioneurotic edema Several of these cases he had followed closely, making repeated blood examinations, and in none had he ever noticed more than a slight leucocytosis, and he had never seen but a normal differential blood count. As a result of his experience with these cases he was inclined to believe that the complete examination of the blood would form an aid in the differential diagnosis between this disorder, Henoch's disease, and the acute disorders of a surgical nature. He recalled a case that he had seen fifteen years ago. No diagnosis had been made. The child was ten years old. He had an attack of appendicitis, but no operation was performed. One day, while in apparently good health, he complained of violent pain in the abdomen. He had very little temperature but he looked very ill. No tumor could be palpated. The abdomen was very sensitive. The bowels had not moved for two days. The tongue was coated. The child was seen by a consultant and no diag-

nosis was made, although they were suspicious of an abdominal obstruction, possibly an intussusception. That same day the child was seen by a surgeon who recommended an exploratory laparotomy. The child vomited all that day and at ten o'clock that night vomited blood. Every effort to move the bowels failed. Soon fecal vomiting occurred. Operation was then done. The appendix was found to be normal and no intestinal obstruction was found after a very diligent search. There were, however, a large number of ecchymotic spots on the peritoneal covering of the intestines and mesentery, and parts of the intestine, six, seven and eight inches long, were in a state of spastic contraction. Other parts appeared to be edematous. The child's condition was so bad that the abdomen was rapidly closed. The vomiting continued and eight or twelve days after the operation the child died. No autopsy was allowed, but on inspection through the abdominal wound it was noted that the punctate spots had disappeared. He believed this to have been a case of Henoch's purpura, although no such diagnosis was made at the time.

SECTION ON PEDIATRICS.

Stated Meeting, Held February 11, 1909.

DR. ELI LONG IN THE CHAIR.

A Case of Acidosis in a Girl of Nineteen Months; Death.—Dr. HENRY E. HALE reported this case. He said that his first experience with diacetic acid in the urine had been five years ago, the patient being a baby, ten months old, who had cyclic vomiting. Since then he had had seven other cases, and the only one that terminated fatally was the subject of his report. As a result of this experience, instead of considering diacetic acid simply an interesting finding in the urine, he regarded it as an important guide in the treatment of acidosis, and an indication for the immediate exhibition of from two to four teaspoonfuls of milk of magnesia, repeated in a few hours; he also ordered sodium bicarbonate or carbonate, by mouth, rectum, or both, encouraged the taking of water, and stopped all food for from twenty-four to forty-eight hours. If he should see another case, he said he would advise hypodermoclysis of a sodium solution, probably a bicarbonate solution of about 0.8 per cent. His prophylactic treatment consisted of a diet low in fats, milk of magnesia as a laxative when such was needed, and the administration of calomel at regular intervals of two or three weeks, followed for one, two, or three days by nightly doses of sodium phosphate and sodium salicylate. The very first sign of malaise or poor appetite was the signal for a urinary test for diacetic acid. Care should be taken not to mistake a drug reaction for that of diacetic acid. He first saw the patient on November 17, and death occurred November 21. The child had been fed almost entirely on milk and cereal. The cereal with cream poured from the top of a quart bottle of milk made up the greater portion of her breakfast. The other four meals consisted of whole milk, a little bread and butter, and possibly once a week a potato. For a month or more previous to her fatal illness she would gag as though to vomit every morning. On November 14 she appeared perfectly well, but on the day following she had no appetite and some fever. There was no vomiting. She was given a dose of castor oil and the bowels began to move the next morning. The first two stools consisted of fecal matter; the others, numbering twenty-three that day and sixteen the next, consisted of water, blood, and mucus. The accuracy of this statement of the parents he questioned. On November 15, 16, and 17 she was fed solely on mutton broth. At no time had her thirst been satisfied. No medicine was given her but subnitrate of bismuth. The child was apparently well nourished and bright. Her pallor was the most striking feature. She did not appear very ill. The rectal temperature was 101.6°, pulse 132, and respirations 44. Dr. Hale directed that she should be taken outdoors and that no food should be given her until he saw her again. He ordered salol and powdered opium in lactose, and told the mother to allow her as much water as she wished, adding a half teaspoonful of sodium bicarbonate to the glass. He asked for a specimen of the urine. On November 18 the mother telephoned that the child had not voided any urine, although she had taken large quantities of water. She was twice placed in a tub of hot water and given a high enemata through a catheter, but without the desired result. That afternoon the child was apparently improved, but there was a distended bladder reaching two inches above the symphysis pubis. This distention was relieved by the catheter, and about six ounces of clear urine was obtained. This contained no albumin, casts, sugar, or indican, but it did contain large amounts of diacetic acid, which was differentiated from any reaction due to salicylic acid. On November 19 the child seemed decidedly better. The quantity of sodium given was not increased because there seemed no indication for it. Had a specimen of urine been obtainable it would probably have given a valuable suggestion to the contrary. On November 20 she was nauseated but did not vomit. She had had many yellow, watery, mucous stools with scarcely any odor. Her appearance was not alarming. On November 21 small gray ulcers developed on the margin of the tongue. The urine was lost in the stools. In the afternoon he was called in and found the child *in extremis*, unconscious, pupils unequal, strabismus marked, and occasionally convulsive movements occurred. The temperature was 105.8°, pulse imperceptible at the wrist but 208 at the apex, and respirations of the Cheyne-Stokes type. Death was ushered in with a convulsion.

Congenital Hypertrophic Pyloric Stenosis.—Dr. J. FINLEY BELL of Englewood presented this case. The child was born October 7, 1908. She was nursed regularly, but from the beginning regurgitated more and more after nursing. Notwithstanding the vomiting, at the end of the third week she weighed eleven pounds; then her weight remained stationary for about two weeks, when she began to fail. The bowel movements were never large, were infrequent, olive green or dark brown, and foul. The urine was scant and left a reddish stain. Various methods of nursing were tried, but the symptoms continued. By December 1 the symptoms had become more severe and were so characteristic of congenital pyloric stenosis that Dr. Jacobi was called in consultation and confirmed the diagnosis. By December 11 he was convinced that operation would have to be resorted to. Two operations were performed by Dr. Curtis (see below). The child left the hospital December 24, and had continued to improve ever since. The idea that infants did not bear operations well should be modified. Cases of pyloric stenosis not readily relieved by medical treatment should be operated upon before the child was too reduced to stand surgical treatment.

Partial Pylorectomy for Fibromata in an Infant Nine Weeks Old.—Dr. B. FARQUHAR CURTIS made this report. The history of this patient had just been related by Dr. Bell. The operation was of interest because it offered a possible method for the removal of benign tumors of the pylorus without opening the cavity of the canal and without entirely separating the stomach from the duodenum. The pylorus was isolated by gauze packing and was found to be the seat of a tumor which occupied principally the free border, although there was some thickening of the walls in the entire circumference. The tumor was covered with normal peritoneum, was densely hard, and

about one centimeter in diameter, rounded and tapering to the normal tissues on all sides without definite demarkation. The mucous membrane could be easily detached from the inner surface of the tumor; he decided to leave this intact and to excise only the muscular and peritoneal coats, leaving the superior border of the pylorus, corresponding to the lesser curvature of the stomach. The mucous membrane was not divided, but was bluntly peeled from the internal surface of the part removed so that it was left as a thin sleeve. The superior or attached border of the pylorus was left intact, forming a bridge about one-half a centimeter long and the same in width. The incision across the duodenum measured about two centimeters, the one across the stomach between two and three centimeters, but the gastric and duodenal borders were drawn together without difficulty in spite of the difference in length of these incisions. The operation lasted thirty-six minutes, including an interruption of ten minutes due to defective respiration and rigidity. About one hundred grams of ether was given in all. The tumor involved only the muscular coats, and proved to be a fibromyoma. The vomiting became as severe as before the operation, and the appearance of a considerable amount of broken-down blood clots seemed to indicate that reactionary swelling of the sleeve of the mucous membrane and perhaps the formation of a hematoma beneath it had produced a complete obstruction of the enlarged orifice. As time did not relieve this obstruction and as the child was rapidly losing ground, it was decided to open the wound and to restore the patency of the canal. Four days after the first operation the second operation was performed. The catgut in the skin had been prematurely absorbed under the strain of the repeated vomiting and the edges of the incision had separated. The wound in the pylorus was very firmly closed by plastic material and the external layers, instead of being stretched apart, were more inverted than they were originally. Adhesions were separated and the redundant mucous membrane was cut away. Care was taken not to invert the wall of the stomach as strongly as had been in the first operation, and when the sutures were all inserted the air in the stomach was driven through into the intestine, thus proving the patency of the canal. Dr. Curtis expressed himself in favor of chloroform as an anesthetic in young children. The pulse after the operation was 144, respiration 46, and the evening temperature 103.2°. Feeding by the stomach was begun very early, owing to the fact that the general condition of the child was so bad. Water was given one hour after the operation and mother's milk three hours after. The threatened collapse justified a violation of the rule to keep the stomach empty. It might be that this precaution was not so necessary as had been supposed. This method greatly simplified resection of the pylorus, where it was not necessary to remove the part entirely. By pinching up the redundant mucous membrane into a transverse fold and rapidly suturing the base of the fold the redundant part could be cut away without cutting into the lumen. The sutures should be introduced first at the angle of the wound on the posterior wall of the pylorus. The danger of recurrence of the fibromyoma was not imminent enough to require a very wide removal of the sac. It was all-important to make the operation as easy and as rapid as possible in these young children, and if recurrence should take place a second operation was preferable to running the risk of losing the child by a too prolonged operation.

Dr. John Douglas said that carmine and charcoal might be of use in determining whether or not stenosis was complete. The presence of curds in the feces would also be of diagnostic value. Even though the vomiting might be continuous, if carmine and charcoal passed through it would prove that the pyloric opening was patent. In regard to the etiology, he said that one could scarcely imagine spasm producing such a hypertrophy of the pylorus. The case which Dr. Bell reported was more like a tumor. Dr. Douglas cited several cases from the literature in which the condition could not have been due to spasm or irritation. In one case the thickening was due to thickened muscular fibers. He thought the cases referred to differed from what was found in adults, where, in doing a gastroenterostomy, there was no sign of thickening or spasm; it hardly seemed possible that they could belong to the same class of cases where there was a congenital non-development as well as spasm and hypertrophy. There seemed to be much diversity of opinion as regarded treatment. Hutchison had reported fourteen cases with thirteen recoveries. There was a certain number of cases in which operation was necessary, as in spasm, thickening, hypertrophy or congenital thickening. The most recent statistics gave 114 cases operated upon; in these divulsion was done in 27 cases with a mortality of 52 per cent.; gastroenterostomy in 69 cases with 54 per cent. mortality; pyloroplasty in 17 with 53 per cent. mortality; and pylorectomy in one case with 100 per cent. mortality. The most recent statistics were in 22 cases with a mortality of 41 per cent. for pyloroplasty. If these cases could be recognized earlier the chances for the patient would be better. A submucous resection of part of the thickened tissue without opening the cavity of the stomach or duodenum, as done by Dr. Curtis, or a submucous pyloroplasty, as done by de Ribes, should in the future give so much better results than had been obtained in the past that the physician would not hesitate to refer to the surgeon those cases which did not respond to treatment.

Dr. Henry Koplik said that, in this case, it was fortunate the child was operated upon, but that this did not seem to be a typical case of hypertrophic stenosis of the pylorus, for, as Dr. Curtis said, a transverse section through the pylorus would have resembled somewhat a signet ring, with an obstructed center displaced far from the seal. This case was a tumor of the pylorus, and had nothing in common with hypertrophic stenosis of the pylorus. Dr. Koplik thought that Dr. Douglas had stated his position in a very liberal way; they were coming to the belief that these cases should not first come under the care of the surgeon. Ibraham, Feer, Koplik, and others had shown 80 per cent. recoveries with medical treatment. Heubner gave 90 per cent. recoveries. Ibraham spent three or four years in the study of this disease, and stated that by medical means he had cured 80 per cent. of his cases. When there was spasm, with but little hypertrophy, the spasm usually subsided before the case came to operation. Dr. Koplik said that he had had 20 cases of hypertrophic stenosis of the pylorus. In some of these cases where surgeons wished to operate the tumor could be felt and peristalsis was marked, yet these cases went on to recovery without operation. There might be considerable stenosis with spasm and still the patient would get well. Medical men looked at these cases in different ways. Some felt that they could not put these children under the knife in true congenital hypertrophic stenosis except as a desperate measure. He had had some very severe cases, and two out of three operated upon died. In one of these the child was in a fairly good condition, but developed a mastoiditis and died. Dr. Koplik related several cases in which the tumor could be distinctly felt and still the children recovered without operation. If there was vomiting of blood with collapse and one felt that something must be done, operation might be resorted to, but he had seen cases where there was vomiting of blood and yet he did not advise operation and the children recovered.

Dr. Clarence A. McWilliams said that medical treatment should not be persisted in too long if the surgeon was to be called in. Dr. Koplik had said that 60 per cent.

of these cases could be cured by medical treatment, but it was only by surgery that some of the remaining 40 per cent. could be saved. Statistics of operations showed 40 to 50 per cent. recoveries, which was not bad, considering the condition of some of the patients at the time of operation. This, too, when stomach surgery was in its developmental stage; better results could be expected in the future. If proper medical treatment were instituted early in these cases probably the majority would get well, but some cases resisted intelligent medical treatment, and these, together with those that came to treatment late in the development of the disease, were proper cases for the surgeon. The most important indication for operation was progressive and obstinate loss of weight. The most favorable statistics were those of Nicoll (*Glasgow Medical Journal*, 1908), who operated upon thirteen cases with only two deaths, a percentage of 15.2. He operated upon the pylorus, making a V-shaped incision through the muscular fibers, but not through the mucous membrane. Divulsion of the pylorus was performed through a separate incision in the stomach. The V was then sutured so as to form a Y. This was a simple operation, and could easily be performed. It was probably necessary only to paralyze the sphincter of the pylorus for some time in order to effect a cure of the stenosis, as it was probable that hypertrophy of the muscle alone in itself never completely closed the pylorus.

Dr. Bell said that some of the cases reported to be cured remained to be proven. He told of one case thus reported that died later from another cause, and at autopsy pyloric stenosis was found to exist. It was not his custom to wash babies' stomachs a great deal, as it taxed their strength too much. In regard to the growth being a tumor, in the case reported, he said that it was not a true hypertrophy; it was largely local, and the microscopical sections showed it to be composed of simple unstriped muscular fibers perfectly normal. The mortality of surgical cases, including medically neglected ones, was 50 per cent. In the case reported the stenosis was complete; it was impossible to drive gas or water through the pylorus.

A Study of the Eye in Mental Defectives.—Drs. L. Pierce Clark and Marten Cohen presented this paper. They said the fact that fundus examinations had been so little emphasized in examinations in idiocy might possibly be accounted for by the negative findings of Moss, who examined 116 feeble-minded children in Berlin. This study showed but two cases with alterations in the fundus. Of 528 cases examined by Gelfe but 27.5 per cent. showed normal eyes. Gelfe's idiots showed a percentage of 43 for normal idiot fundi as compared with 56 for weak-minded, and 83 for simply backward children. Their findings were quite in accord with those of Gelfe. They had undertaken this study because Cline and Tyson, in inquiring into the nature of eye changes, found in dementia precox that a fairly constant eye syndrome was present in that mental disorder embracing among other signs a mild grade of optic degeneration, which was thought to be of autotoxic origin. In the discussion of this paper it was brought out that in the occurrence of optic nerve changes in dementia precox the syndrome was due to a strong tendency to neural degeneration, rather than to a particular autotoxin. It was thought that an investigation of the allied states of mental degeneracy, such as imbecility and idiocy, might throw light on the subject. In the present study fully three-fourths of all the cases of idiocy showed varying stages of a retrobulbar neuritis of a degenerative character. A second object of inquiry was to see whether there were pathognomonic structural defects in the eyes of feeble minded children and idiots comparable with other grosser defects mental and physical. The negative findings in this part of the work had been disappointing. It seemed that the eye defects did not extend beyond those of mere functional incompetency of vision in idiocy. The defective central enervation might account for this lack of visual acuteness. The study was made in the Randall's Island service where there were 1,000 cases from which to select. Fifty cases each of feeble minded, imbeciles, and idiots were chosen, but of these only 129 could be examined carefully. The imbeciles were of the unteachable grades, but able to care for themselves and help a little about the ward. The idiots were of the lowest type of helpless cases in the institution. Only idiopathic cases were chosen. Examination of the eyes showed external changes in but few cases; unilateral ptosis was noticed in two feeble-minded children; strabismus was found in one feeble-minded child. The pupillary reflexes to light, accommodation, etc., were present in all, but sluggish in idiots. One idiot showed rigidity of the pupils. Acuity of vision, fields of vision, and refractive errors could not be determined owing to lack of cooperation due to the mental defect. By using the retinoscope there were found 4 cases of myopia, 3 of hypermetropia, and 15 of astigmatism. Ophthalmoscope examination was made by means of the indirect method, using a candle as the source of light. In only 106 of the 129 cases could the fundus be properly examined. Only 9 of 29 feeble-minded children showed normal fundal appearances. Pallor of the temporal half and odema of the nasal half of the disc were present in 7 cases. There was slight indistinctness of the disc in two cases, and well-marked neuritis in one. The early stage of atrophy was found in six cases, but advanced atrophy was not found in any case. In 4 cases there was dilatation of the veins. Of 24 imbeciles examined, 15 had eye grounds normal in appearance. Four showed pallor of the temporal half and odema of the nasal half of the disc. In one case there was slight indistinctness of the disc. One case showed well marked atrophy. There were 53 cases examined in the group of idiots and all but 11 showed a normal fundus. In 13 cases temporal pallor and nasal edema were present. In one case there was general congestion of the entire disc; in eight there was generalized pallor of the discs; in three there was optic atrophy; in one, dilated veins. One patient each showed, choked disc, thrombosis of the central vein, retinal congestion, retinal hemorrhage. The conclusion reached was that there was a well marked tendency to neural as well as psychic degeneration in the great majority of all grades of idiots.

Dr. Charles H. May said that he had been in the service at Randall's Island nineteen or twenty years ago when there were no facilities for making examinations, but he had made observations on 60 cases. He had been unable to make examinations of the fundus. He had found a great many external anomalies and in this respect his results differed from those which the writers of the paper had reached. He had found that all the material used for squint operation was derived from the feeble-minded and idiot wards; in fact, 10 per cent. of all such patients had squint. Another feature in these cases was the large number of instances of anisometropia, variations in the conditions of refraction in the two eyes. Only gross errors could be taken account of at that time as retinoscopy was not in vogue.

Dr. Henry Hawkins Tyson said that he had made observations on about 40 cases and that his interpretation of the ophthalmoscopical pictures found during examination differed somewhat from those reported in the paper. In the feeble-minded cases the appearances of the fundus oculi varied very slightly from normal; the increased color in the veins found in some cases was such as was found in cases of autointoxication. He found no cases in which the margins of the papillæ were blurred nor indications of an optic neuritis. In a few imbeciles evidences of arteriosclerosis were found in the fundi. In a majority of the cases classified as idiots an atrophy of the optic nerve was found. In cases of post neuritic atrophy associated with

deformities of the skull, the cause of the atrophy was a mooted question, whether the diseased nerves were produced directly by the deformity, or whether both rose from a common cause, or whether the two conditions were coincidental. In Friedenwald's report of 17 cases (12 were oxycephalic) the ophthalmoscopic findings were given in 15 cases of which thirteen (13) had either an optic neuritis, or a post-neuritic atrophy; two cases of optic atrophy were not classified. The orbits in some of these skulls were very shallow and the eyeballs protruded so that at first they might be taken for myopic globes. In the cases of optic atrophy, the atrophy was of the greyish post-neuritic variety, similar to that seen in cases following infantile cerebral disease. He was inclined to the opinion that the optic nerve lesion was the result of some intracranial inflammation, in addition to the degeneration.

Dr. Marten Cohen said that the report was not conclusive because of the great difficulty encountered in the examination of this class of patients. In some cases it was impossible to state definitely by ophthalmoscopic examination whether the atrophy was primary or secondary. Only a microscopical examination of the disc could decide this point. In cases where they had found a normal fundus, the optic nerve tract probably escaped the general cerebral degeneration.

Observations on the Use of Lactic Acid Bacilli at the Babies' Hospital During the Summer.—Dr. Charles Gilmore Kerley presented this paper. He said that for many years buttermilk had been used in Holland in infant feeding and various observers had reported good results. During the summer of 1908 the lactic acid bacillus had been used in the service of Dr. La Fétra and himself in the Babies' Hospital. The milk was prepared in the diet kitchen of the hospital using one tablet containing a pure strain of lactic acid bacillus, dissolved in four ounces of water and mixed with one quart of milk. The mixture was then allowed to stand for from twenty-four to forty-eight hours, when it was diluted with water, cereal water, and milk sugar or cane sugar. The child's caloric requirements were considered in each case. This soured milk was used in 34 cases, full milk being employed in 30 cases, and skimmed milk in four. The first group treated were distinctly feeding cases, from one to sixteen months of age. In 11 of these full milk was used and in four skimmed milk. All but one of the 11 using full milk lost in weight and that one gained one-half ounce in two weeks. One lost four ounces in two days. Another child in fair condition lost six ounces in three days without a sign of illness and after taking the food well. The four that took the soured skimmed milk fared as badly. Three failed rapidly and died in from two to nine days from inanition. The results were so disastrous that further observations on feeding cases were abandoned. The children were not made ill by the soured milk, but simply faded away. The second group treated comprised babies who were given the soured milk after intestinal diseases. It was well-known how difficult it was after a severe attack of summer diarrhea to bring a baby back to a cow's milk diet. The soured milk was used in 19 cases after the subsidence of acute symptoms, when freer feeding might with propriety be substituted. These babies ranged in age from one to fourteen months. This milk was absolutely refused by two babies. In four others a very rapid loss in weight made it necessary to discontinue the milk after using it from two to four days. Only four of the children gained in weight, one gained 7 ounces in 16 days, one two ounces in 16 days, one 10 ounces in 15 days, and one, 1 ounce in six days. But two in the series made a satisfactory showing. The usual methods of resuming stronger feeding gave results incomparably better and further experiments with this method of feeding were discontinued.

Dr. Josephine Hemenway said she had been impressed by two points at the Babies' Hospital. First that children brought to the hospital in a condition by no means hopeless, but who were not gaining, if fed on soured milk, changed so suddenly and failed so rapidly that one could pick them out in going through the ward. The second point was that this food failed to fatten the children; none of them showed any improvement so far as putting on fat was concerned; and this was especially true of the soured skimmed milk. Their experience with skimmed milk showed that it had no value as a food unless some other element of the food was increased, as for instance, sugar. In a small series of cases of winter gatrointestinal trouble, an initial purgative was given, then two days' starvation and then fat-free acidified milk for three or four days. The character of the stools had changed rapidly for the better under this treatment. The children were then placed on regular milk modifications. In several cases of chronic intestinal indigestion in older children the acidified milk seemed to give good results, but it was given in connection with other articles of diet.

Dr. L. E. La Fétra said that there was no doubt that the children fed on this acidified milk did worse, as a rule, than when on the usual diet. The results of the observations had been a great disappointment to him. It was almost impossible by rectal injection of a suspension of the bacilli to get them as far as the ascending colon, where they would do any good. If they could be used by the mouth in sufficient quantities and in good culture media, they might possibly be carried through the tract and exert a favorable action. He felt that there was a distinct field for buttermilk in cases in which fat was not well borne, and those with putrid stools, which were alkaline rather than acid. He had had good results by using the buttermilk for a period of a week or ten days, using it for the purpose of changing the character of the intestinal contents. When the stools became normal he changed the diet.

Dr. Henry Dwight Chapin said that whatever was reported of infants in hospitals should be taken with a great deal of scepticism, as babies in hospitals did not do well on anything. The hospital was not a good place for them. The hospital should be the round-up for those babies acutely ill, but they should be sent out as soon as possible. He had not given so much attention to the stools; as long as the baby gained in weight it was not wise to interfere with the food. If the child lost in weight and the stools were bad, he at once changed the diet. He was of the opinion that buttermilk had a restricted use. Babies did not like it, and the baby was the one to decide what it would take.

Dr. Elias H. Bartley said that his worst trouble had been to get children to partake of this food; he had only succeeded in getting two children to take it. Both of these children improved under it for two days in one case and four in the other. Then they refused to take it longer. He had tried it with some success in private practice and thought that it would cut short acute troubles unless they were due to lactic acid fermentation or lactobutyric fermentation. He had not tried it in healhy babies and saw no reason for doing so. The reports of the bacteriological examinations of the tablets at the Hoagland Laboratory had been disquieting, for almost all the cultures were found to be mixed cultures and not pure ones. He thought the use of milk did tend to reduce the amount of fermentation in the intestinal canal. He had used lactic acid in 5 per cent. solution for several seasons with good results. Recently he had used whey slightly soured with lactic acid and thought it gave as good results as soured milk. In some respects New York did not agree with the outside world. For instance, it was claimed in Europe that babies did well on whole milk. They did not do well on it in New York. In some localities they fed babies on high-fat milk, but they could not do it in New York.

State Medical Licensing Boards.

STATE BOARD EXAMINATIONS QUESTIONS.

Oklahoma State Board of Medical Examiners.

Muskogee, November 10, 1908.

ANATOMY.

1. Name and give location of four ductless glands.
2. What structures pass through the (*a*) jugular foramen, (*b*) foramen magnum?
3. Give origin, insertion, and nerve supply of the following muscles: Biceps, sartorius, gastrocnemius.
4. Give regions of the abdomen and their contents.
5. Mention all the abdominal viscera not completely invested by peritoneum.
6. Name the structures to be divided in operating for strangulation of an oblique inguinal hernia.
7. Name the cranial nerves in their order; give the function of each.
8. Give relation of the femoral artery; give its branches.
9. Name the bones of the cranium and the face; give articulations of each.
10. Give fetal circulation.

BACTERIOLOGY.

1. Into what varieties or species are bacteria divided?
2. How do bacteria multiply? Describe this process in the case of cocci, bacilli, and spirilla.
3. What conditions are required for the proper development of bacteria? Give the most favorable temperature for their growth.
4. What pabulum is necessary for the life of bacteria? Explain how they live in a saline solution.
5. Name culture media: (*a*) two liquids, (*b*) one solid. How are they prepared?
6. Describe the method of inoculating: (*a*) liquid media, (*b*) solid media. What do you understand by (*a*) slant culture, (*b*) stab culture?
7. Give a good method for the cultivation of anaerobic bacteria.
8. Name four pyogenic bacteria; give individual features of each.
9. Give the pathogenesis and morphology of the gonococcus. Name its discoverer.
10. Name the three varieties of malaria parasites found in the human blood; give the life cycle of each.

OBSTETRICS.

1. What changes occur during pregnancy in the external genitals and vagina?
2. When should a healthy child be weaned?
3. Give treatment for severe flooding after birth of child.
4. Describe vaginal and vulvar lacerations resulting from labor; give proper time and mode of repair.
5. Under what circumstances would you be justified in inducing premature labor, and at what period?
6. What are the subjective signs of pregnancy?
7. Give the uses of ergot, cinnamon, mistletoe, and quinine in obstetrics.
8. Give cause and treatment of eclampsia.
9. How may the knee be distinguished from the elbow when presenting?
10. What is the diagnosis of false from true labor pains?

CHEMISTRY.

1. Define (*b*) chemistry; (*c*) organic, (*d*) inorganic.
2. What is an atom? Give an example.
3. What is a molecule? Give an example.
4. Give a test for pure water.
5. Give test for sugar in urine.
6. What is H_2O, HCl? Give symbol for sulphuric acid
7. Give symbol for peroxide of hydrogen.
8. Give symbol for silicon, antimony, carbon, gold, copper.
9. Define and give example of the terms (*a*) acids, (*b*) bases, (*c*) salts.
10. Define the term "an alkaloid"

PATHOLOGY.

1. What pathological changes occur in cirrhosis of the liver?
2. What do you understand by anesthesia?
3. What is the cause of anemia?
4. What is the difference between a malignant and non-malignant tumor?
5. Give difference between albuminuria and diabetes.
6. What is the pathological condition of the kidneys in nephritis?
7. What is pterygium of the eye?
8. What is inflammation, and how characterized?
9. What is the difference between a carbuncle and a boil?
10. Give difference between cancer and ulceration of stomach and diagnosis of each.

MEDICAL JURISPRUDENCE.

1. Enumerate the causes of sudden death.
2. Give an example of criminal malpractice.
3. Give the signs of death by morphine.
4. Give the differences in an incised wound made before and one after death.
5. On what findings would you testify that rape had been committed upon a virgin?
6. Give the cause and duration of rigor mortis.
7. Give the methods of identification of blood stains.
8. To what kind of a crime does strangulation mostly point? Also hanging?
9. Define infanticide. State what means should be resorted to in order to establish it.
10. How would you proceed to examine a case of suspected criminal abortion?

SURGERY.

1. Give the symptoms, diagnosis, and treatment of impacted fracture of the neck of the femur.
2. Describe an amputation of the leg at a point about midway between the knee and foot.
3. What is the differential diagnosis between concussion and compression of the brain?
4. Give symptoms and treatment of dislocation of the semilunar cartilages of the knee-joint.
5. Describe the manipulation for reduction of a posterior luxation of the hip-joint.
6. Give the symptoms and treatment of carbuncle.
7. Describe in detail the treatment of a case of secondary syphilis.
8. What do you understand by septicemia, septic intoxication, and septic infection.
9. Describe aneurysm, its varieties and symptoms.
10. Describe the symptoms of pyothorax and an operation for its relief.

HISTOLOGY.

1. Describe the larynx structurally considered.
2. Define a cell, and name parts of same.
3. What is cartilage? Name three varieties.
4. Describe the striated muscle, and tell where it is found.
5. Of what is nerve tissue composed? From what layer is it derived?
6. Name the parts composing the circulatory system.
7. What kind of a gland is the spleen structurally considered? Describe its capsule.
8. Name the membranes of the central nervous system.
9. What is the thymus body? Of what is it composed in its early stage?
10. What tissues are derived from the entoderm?

TOXICOLOGY.

1. What poison did this man take?

The amount swallowed was about a teaspoonful. About two hours after taking the poison he was seized with vomiting, and continued to vomit large quantities of black blood almost without interruption for the next six hours, after which the color of the vomited blood changed to a bright red under treatment and became much diminished in quantity and frequency. When seen, about eight hours after taking the poison, his breathing was very labored and accompanied with raucous sound. He kept his lips apart, but they were not scarred in any way, though the tongue, especially at the posterior part of the dorsum, was very much wrinkled and burnt. Complexion pallid, feet and hands cold. Pulse 74; respiration 26; temperature under axilla normal. He had little pain except that caused by dyspnea and a constant feeling of soreness about the sternum one inch above the xiphoid cartilage. He was never unconscious; he spoke with difficulty and with a very hoarse voice. Patient improved somewhat under treatment, but died suddenly in collapse, twenty-three or twenty-four hours after taking the poison.

2. Give detailed account of post-mortem appearance caused by nitric acid.
3. Give Reinsch's test for arsenic.
4. Give antidote for acute mercurial poisoning.
5. Give symptoms of chronic lead poisoning.
6. Give tests for zinc sulphate.
7. Give treatment for poisoning by ferrous sulphate.

8. Give treatment for poisoning by oxalic acid.
9. What poison did this man take?

After taking the poison the patient complained immediately of a feeling of intense burning in the gastrointestinal tract followed in fifteen minutes by copious vomiting. The matter vomited contained part of the poison. Dejections followed in twenty minutes after mixture was swallowed, and both vomiting and purging continued at frequent intervals until death took place. The discharges, though involuntary, were attended with great suffering. Prostation was extreme, resembling the collapse of malignant cholera. Thirst was very great. Mind not affected, but for three hours before death vision was so much affected that he was unable to recognize acquaintances.

10. Describe poisoning by opium and morphine.

PHYSICAL DIAGNOSIS.

1. Give the abnormal heart sounds and the point of greatest intensity of each.
2. Give method of examination in suspected pleuritic effusion.
3. Give physical signs and method of examination in ascites.
4. How may pleuritic friction sounds be distinguished from râles in the bronchial tubes?
5. Differentiate cardiac dyspnea, nervous dyspepsia, and asthma.
6. Make differential diagnosis between bronchiectasis and pulmonary tuberculosis with cavity.
7. By what signs may free air in the abdominal cavity be recognized?
8. What conditions give rise to bronchial breathing, and in what diseases may it be heard?
9. Differentiate between a pleuritic and pericardial friction sound.
10. Give the normal boundaries of the liver.

PRACTICE OF MEDICINE.

1. What form of pneumonia is most prevalent in children? Give diagnosis and treatment.
2. What are the symptoms of membranous croup? (*b*) Of spasmodic croup? (*c*) Differentiate and give treatment.
3. What do you understand by "catching cold," and what are the predisposing causes and what is the prophylaxis?
4. Give symptoms, diagnosis, and treatment of typhoid fever.
5. (*a*) Diagnose a case of appendicitis. (*b*) Give medicinal treatment. (*c*) When would you advise an operation?
6. What is the difference between infectious and contagious diseases? Name one of each.
7. What disease does empyema follow, and how would you diagnose it?
8. State the age of a patient and give treatment for diphtheria in detail.
9. Give symptoms and treatment of uremic poison.
10. Give symptoms, diagnosis, and treatment of meningitis.

MATERIA MEDICA AND THERAPEUTICS.

1. Give the different methods of administering medicine and describe your law of cure.
2. What are the remedies used in scarlet fever, and what are the indications that guide you in their use?
3. Name the remedies used in pneumonia and the symptoms that indicate the use of each.
4. Name three different drugs that have direct affinity for the heart, and describe the modus operandi of the action of each.
5. Discuss comparative value of vegetable and mineral cholagogues.
6. Name remedies that are used in rheumatism, and symptoms calling for them.
7. Give dosage and uses of the officinal salts of copper.
8. Write a prescription for intercostal neuralgia.
9. Discuss the action of alcohol upon the human system.
10. Give habitat, preparations, dosage, and uses of ten principal remedies you carry in your medicine case.

PHYSIOLOGY.

1. What is physiology?
2. What causes the arterial circulation?
3. Give the different stages of digestion and the different fluids essential to same.
4. Give the contents of the stomach at the close of gastric digestion.
5. Give the coatings of veins and the forces that cause the circulation in same.
7. How does serum differ from the liquor sanguinis?
8. Give the functions of the liver.
9. What is albumin, where found, and what does it contain?
10. What are the functions of the kidneys?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

OKLAHOMA STATE BOARD OF MEDICAL EXAMINERS

Muskogee, November 10, 1908.

ANATOMY.

1. *Four ductless glands, with location:* (1) The spleen; situated in the back part of the left hypochondriac and epigastric regions, being covered by the ninth, tenth, and eleventh ribs on the left side.

(2) The thyroid; situated on the sides and in front of the upper part of the trachea, and extending upwards on each side of the larynx.

(3) The suprarenals; situated in the back part of the abdominal cavity, behind the peritoneum, one on the upper extremity of each kidney, and slightly also on the inner and anterior surfaces.

(4) The carotid gland; situated generally in the carotid bifurcation.

2. Structures passing through: (*a*) *Jugular foramen*: Inferior petrosal sinus, lateral sinus, meningeal branches of occipital and ascending pharyngeal arteries; glossopharyngeal, pneumogastric, and spinal accessory nerves.

(*b*) *Foramen magnum:* The medulla and its membranes, vertebral arteries, spinal accessory nerves, anterior and posterior spinal arteries, and the occipitoaxial ligament.

4. The regions of the abdomen and their contents are shown in the following table. It is to be remembered that the contents will vary according to the position of the lines drawn; these are arbitrary, and nearly every writer differs from every other. In the following table the superior horizontal line extends between the cartilaginous ends of the tenth ribs, the inferior between the anterior superior iliac spines. The vertical lines pass upward from the iliopectineal eminences, at right angles, to the upper horizontal line.

The viscera situated in each region are as follows:

RIGHT HYPOCHONDRIAC.	EPIGASTRIUM.	LEFT HYPOCHONDRIAC.
Liver.	Liver.	Stomach.
Right kidney.	Stomach.	Spleen.
Hepatic flexure.	Gall bladder.	Left kidney.
Colon.	Duodenum.	Splenic flexure.
	Pancreas.	Colon.
RIGHT LUMBAR.	**UMBILICAL.**	**LEFT LUMBAR.**
Right kidney.	Transverse colon.	Small part of left kidney.
Ascending colon.	Duodenum and small intestines.	Descending colon.
Ileum.	Great omentum.	Small intestines.
RIGHT ILIAC.	**HYPOGASTRIC.**	**LEFT ILIAC.**
Cecum.	Small intestines.	Sigmoid colon.
Appendix.	Bladder in children.	Small intestines.
Last coil of ileum.	Distended bladder in adults.	
	Pregnant uterus.	
	Sigmoid colon.	

5. The abdominal viscera *not completely* invested by peritoneum are: Duodenum, cecum, ascending colon, descending colon, rectum, bladder, vagina. The pancreas, kidneys, and suprarenals are *uncovered* by peritoneum.

6. The structures to be divided in operating for strangulation of an oblique inguinal hernia are: Skin, superficial fascia, intercolumnar fascia, Cremaster muscle and fascia, infundibuliform fascia, subserous areolar tissue, and peritoneum.

7. The special *names* by which the twelve pairs of nerves are generally known are: (1) Olfactory; (2) Optic; (3) Motor oculi; (4) Trochlear or Pathetic; (5) Trifacial; (6) Abducens; (7) Facial; (8) Auditory; (9) Glossopharyngeal; (10) Pneumogastric or Vagus; (11) Spinal Accessory; (12) Hypoglossal.

Functions: (1) Special sense of smell; (2) Special sense of sight; (3) Motor; (4) Motor; (5) General sensation and motor; (6) Motor; (7) Motor: (8) Special sense of hearing; (9) General sensation and special sense of taste; (10) Motor and general sensation: (11) Motor; (12) Motor.

8. FEMORAL ARTERY. *Relations:* Superficial in upper third, being contained in Scarpa's triangle, more deeply

placed in middle third (Hunter's canal). In first 1½ inches is enclosed in femoral sheath. *In front:* Skin, superficial and deep fascia, internal cutaneous branch of anterior crural nerve, sartorius, long saphenous nerve, aponeurotic arch over Hunter's canal. *Behind:* Psoas, profunda vessels, pectineus, adductor longus, femoral vein (at lower part of Scarpa's triangle, and in Hunter's canal), tendon of adductor magnus. *Inner side:* Femoral vein (in Scarpa's space), adductor longus. *Outer side:* Sartorius (in Scarpa's space), vastus internus, femoral vein gets to outer side near ending.—(From *Aids to Anatomy.*)

Branches: Superficial epigastric, superficial circumflex iliac, superficial external pudic, deep external pudic, muscular, anastomotica magna, and profunda femoris (with branches: external circumflex, internal circumflex, and three perforating).

BACTERIOLOGY.

1. The three basic forms of bacteria are: (1) The *coccus,* which is round or oval, and may appear singly, in pairs, in groups of four, in chains, or in bunches. (2) The *bacillus,* which is rod shaped, with the longer sides parallel, and the short ends either straight, rounded, or concave. (3) The *spirillum,* which is spiral.

2. Bacteria multiply by fission, also (sometimes) by sporulation. *Cocci* may divide in one, two, or three directions of space. *Bacilli* divide transversely to their long axis. *Spirilla* divide transversely to their long diameter.

3. Most bacteria require proper temperature, generally at or near that of the body; oxygen is generally needed, those that cannot live without it being called aërobic, and those that can grow without it, anaërobic; nutriment of a proper kind, containing both organic and inorganic material; a slight degree of moisture; a medium of slightly alkaline reaction; and rest. Individual bacteria may require modifications of the above essentials.

4. The pabulum necessary for the life of bacteria is decomposable organic matter (containing carbon and nitrogen); proteid substances.

In a saline solution they probably obtain their nutrition from the decomposition of slight traces of ammonia and the carbon dioxide of the air contained in the water.

5. *Culture media;* two liquid—bouillon, and blood serum; one solid—gelatin.

6. *To inoculate liquid media:* A sterilized platinum needle is introduced into the contaminated material or culture, the smallest amount possible is taken up, and the needle is then introduced into the liquid and gently stirred around.

To inoculate solid media: Take a sterilized platinum needle, dip it into the contaminating material, take up the smallest amount possible, and streak it over the surface of the medium.

Slant culture is a culture made over gelatin which has been allowed to solidify with the test-tube in an inclined position, so as to give a larger surface for inoculation.

Stab culture is a culture made by puncturing the center of a solidified gelatin mass.

7. For the cultivation of anaërobic bacteria, Archinard gives the following method: A culture-tube three-fourths full of the medium is heated to the boiling point and allowed to cool to a temperature in the neighborhood of 40° C.; then a platinum needle charged with the material for inoculation is dipped down to the bottom of the tube. With fluid media, immediately thereafter a layer of paraffin oil is poured on the surface of the liquid before introduction of the cotton plug. With solid media the fluid is allowed to solidify after inoculation, and after solidification the paraffin oil is poured on the surface of the medium. This effectually shuts out the oxygen, and as a rule allows a luxuriant growth of anaërobic bacteria.

8. Four *pyogenic bacteria: Staphylococcus pyogenes aureus, Staphylococcus pyogenes albus, Staphylococcus pyogenes citreus, Streptococcus pyogenes.*

The *Staphylococcus pyogenes aureus* is a small round cell which appears in clusters like a bunch of grapes; its diameter is about 0.8 to 1.0 mikron; it is facultative anaërobic, has no flagella, is not motile, it stains readily with the anilin dyes, and is not decolorized by Gram's method; it forms an orange pigment on gelatin, potatoes, and other media; it also liquefies gelatin.

Staphylococcus pyogenes albus is about the same as the *Staphylococcus pyogenes aureus,* except that it does not form a pigment, and its colonies are of a white color.

Staphylococcus pyogenes citreus is about the same as the *aureus* and *albus,* except that its growth is of a lemon yellow color.

The *Streptococcus pyogenes* is a micrococcus, of spherical shape, and arranged in chains of about thirty or forty cocci (in liquid media), but the chains are much shorter in solid media. Each coccus is about one-half to two mikrons in diameter. It is not motile, does not form spores, does not liquefy gelatin, and stains readily with the ordinary anilin dyes, and by Gram's method.

9. The *Gonococcus* is a diplococcus with a special predilection for the mucous membrane of the urethra; it is sometimes found on the conjunctiva. The appearance is that of two coffee beans; the gonococcus is found in the pus cells, stains with ordinary anilin dyes, but not by Gram's method. It is ærobic, and can be cultivated on human blood serum; it will not grow on gelatin, agar, bouillon, or potato. It was discovered by Neisser.

OBSTETRICS.

1. *Changes occurring during pregnancy in the external genitals and vagina:* Thickening, hypertrophy, congestion, increased secretion from the mucous glands, the vulva is swollen, its opening is patulous, and a bluish tint is observable.

2. A healthy child should be weaned not earlier than the sixth month, and not later than the twelfth month; but there are numerous factors which may cause modification of these limits.

5. Conditions warranting the induction of premature labor: (1) Certain pelvic deformities, (2) placenta prævia, (3) pernicious anemia, (4) toxemia of pregnancy, (5) habitual death of the fetus toward the end of pregnancy, (6) hydatidiform mole, (7) habitually large fetal head.

The most common time for the induction of premature labor is about four to eight weeks before term.

6. The *subjective* signs of pregnancy are: Cessation of menstruation, morning sickness, increased frequency of urination, active fetal movements.

7. *Ergot* is used sometimes after the birth of the head, and during the third stage of labor, to induce uterine contractions, to prevent hemorrhages; also sometimes used in amenorrhea due to plethora.

Cinnamon has been used to ameliorate the nausea and vomiting of pregnancy; it was also formerly used to check uterine hemorrhage.

Mistletoe was formerly used in amenorrhea for uterine hemorrhages, and also as an abortifacient.

Quinine is used to promote uterine contractions, in uterine inertia, as an emmenagogue, also to alleviate after-pains or pains during pregnancy.

8. ECLAMPSIA. The *causes* may be: Uremia, albuminuria, imperfect elimination of carbon dioxide by the lungs, medicinal poisons, septic infection; predisposing causes are renal disease and imperfect elimination by the skin, bowels, and kidneys.

The line of *treatment* as laid down by Edgar is as follows: For *preventive treatment:* (1) The amount of nitrogenous food should be diminished to a minimum; (2) the production and absorption of poisonous materials in the intestines and body tissues should be limited and their elimination should be aided by improving the action of the bowels, the kidneys, the liver, the skin, and the lungs; (3) the source of the fetal metaholic products and the peripheral irritation in the uterus should, if necessary, be removed by evacuating that organ.

The *curative treatment includes:* (1) Controlling the convulsions (by chloroform, veratrum, or chloral); (2) elimination of the poison or poisons which are presumed to cause the convulsions; (3) emptying the uterus under deep anesthesia, by some method that is rapid and that will cause as little injury to the woman as possible.

9. The *elbow* has three prominences, the olecranon process of the ulna and the two condyles of the humerus.

The *knee* has two tuberosities with an intervening depression; the patella may also be felt.

10. *False labor pains* are slight, occur before labor, do not cause dilatation of the os, do not produce a "show."

True labor pains gradually increase in frequency and severity, occur during labor, cause the os to dilate, produce a "show."

CHEMISTRY.

1. *Chemistry* is that branch of science which treats of the composition of substances, their changes in composition, and the laws governing such changes.

Organic chemistry is the chemistry of the carbon compounds.

Inorganic chemistry is the chemistry of such substances as do not contain carbon.

2. *An atom* is the smallest quantity of an element which can enter into chemical action, or that can enter into the composition of a molecule. *Example:* H., one atom of hydrogen.

3. *A molecule* is the smallest quantity of any substance that can exist in a free state. *Example:* H_2SO_4, one molecule of sulphuric acid

4. Pure water would have a specific gravity of 1,000; would be neutral to litmus paper; a few drops evaporated in a platinum dish would leave no solid residue; the boiling point would be 100° C. or 212° F.

5. A TEST FOR SUGAR IN THE URINE: The urine should first be tested for albumin. If this be present, it should be removed by heating the urine to near the boiling point, and filtering from the coagulum.

Fehling's test: Place in a test-tube a few c.c. of the liquid prepared as stated below, and boil; no reddish tinge should be observable, even after five minutes' repose. Add the liquid under examination gradually, and boil after each addition. In the presence of sugar a yellow or red precipitate is formed. In the presence of *traces* of glucose, only a small amount of precipitate is produced, which adheres to the glass, and is best seen when the blue liquid is poured out.

[The reagent must be kept in two solutions, which are to be mixed immediately before use. Solution I consists of 34.653 gms. of crystallized $CuSO_4$, dissolved in water to 500 c.c.; and solution II of 130 gms. of Rochelle salt dissolved to 500 c.c. in NaHO solution of sp. gr. 1.12. When required for use, equal volumes of the two solutions are mixed, and the mixture diluted with four volumes of water.]

6. H_2O is the formula of one molecule of hydrogen monoxide or water.

HCl is the formula of one molecule of hydrochloric acid.

The *formula* for sulphuric acid is H_2SO_4; there is no *symbol* for a compound.

7. The *formula* for peroxide of hydrogen is H_2O_2; there is no *symbol* for a compound.

8. The *symbol* for Silicon is Si; for Antimony is Sb; for Carbon is C; for Gold is Au; for Copper is Cu.

9. (*a*) *Acids* are compounds of an electronegative element or radical with hydrogen, part or all of which hydrogen they can part with in exchange for an electropositive element, without formation of a base. *Examples:* Sulphuric acid, H_2SO_4; nitric acid, HNO_3.

(*b*) *Bases* are ternary compounds capable of entering into double decomposition with an acid to produce a salt and water. *Examples:* Potassium hydroxide, KOH; Calcium hydroxide, $Ca(OH)_2$.

(*c*) *Salts* are substances formed by the substitution of an electropositive element for part or all of the replaceable hydrogen of an acid. *Examples:* Sodium nitrate, $NaNO_3$; Monopotassic sulphate, $KHSO_4$.

10. An *alkaloid* is a basic nitrogenous substance, of alkaline reaction, and capable of acting with acids to form salts in the same way that ammonia does.

PATHOLOGY.

2. *Anesthesia* is the condition in which sensation (general or tactile) is lost.

3. *The causes of anemia* are as follows: (1) *Of the primary anemias:* The cause is unknown, probably it is some form of intoxication. Predisposing causes are: Insufficient and improper food; nervous disturbances, such as violent shock; pregnancy and lactation; gastrointestinal diseases, such as atrophy of the stomach and interstitial gastritis; parasitic diseases, such as ankylostomiasis and bothriocephaliasis; frequently repeated hemorrhages; general diseases, infectious diseases, and intoxications. (2) *Of the secondary anemias:* Bad hygienic surroundings, as insufficient food or food of bad character, inspiration of noxious gases, overwork and crowding; parasitic diseases; exhausting diseases, as cardiac, renal, or gastrointestinal diseases, cirrhosis of the liver, rickets, scurvy; chronic infections diseases, as tuberculosis, syphilis, leprosy, malaria; frequently repeated small losses of blood; overlactation and gestation; toxemia, as Saturnism, mercurialism, and jaundice.—(From Macfarland's *Pathology*.)

4. *Benign tumors* are encapsulated, do not tend to infiltrate the surrounding tissues, do not give rise to metastatic growths, do not tend to recur after removal, do not produce cachexia, and do not have a fatal tendency (except from their location).

Malignant tumors are not encapsulated, tend to infiltrate the surrounding tissues, give rise to metastatic growths, have a tendency to recur after removal, give a cachexia, have a fatal tendency.

7. *Pterygium of the eye* is a triangular fold of membrane extending from the canthus to the margin of the cornea.

8. *Inflammation* has been defined: (1) As the succession of changes which take place in a living tissue as the result of some kind of injury, provided that this injury be insufficient immediately to destroy its vitality.

(2) As the reaction of tissues to an injury.

It is characterized by: Redness, swelling, heat, pain, and impairment of function.

9.

BOIL.	CARBUNCLE.
Affects the skin only.	Subcutaneous tissue also affected.
Has a single opening.	Multiple openings.
Frequently multiple.	Single, but extensive.
Usually occurs from infection of a hair follicle or sweat gland. No albuminuria or diabetes.	Infection with *Staphylococcus pyogenes aureus;* albuminuria or diabetes often accompanies or precedes.
A local affection.	Often severe constitutional symptoms.

10. *Carcinoma of the stomach* does not usually occur before forty years of age, is more common in males, the pain is localized and constant, vomiting is copious and occurs some time after eating; the vomitus contains "coffee ground" material; hemorrhages are common; a tumor may be palpated, and examination of the gastric contents shows absence of free HCl and presence of lactic acid; severe anemia and cachexia are also present.

Ulcer of the stomach is generally caused by injury or bacteria, is most apt to occur between the ages of twenty and forty-five; after eating there is pain localized in the stomach, vomiting occurs soon after eating, hematemesis is common, there is localized tenderness over the stomach, and examination of the gastric contents shows an excess of free HCl.

MEDICAL JURISPRUDENCE.

1. The *causes of sudden death* are: Cerebral hemorrhage; rupture of a gastric ulcer; valvular disease of the heart, especially aortic; angina pectoris; rupture of an aortic aneurysm; suffocation during an epileptic fit; shocks of electricity; sunstroke; mental or physical shock; diabetic coma; uremia; exertion on an overloaded stomach.

2. *Example of criminal malpractice:* The performance of an illegal operation, such as criminal abortion.
